STATE OF CALIFORNIA

Department of Water Resources

SACRAMENTO

February 20, 1959

Honorable Edmund G. Brown, Governor, and
Members of the Legislature of the
State of California
State Water Pollution Control Board
Los Angeles Regional Water Pollution Control Board

Gentlemen:

I have the honor to transmit herewith Bulletin No. 75 entitled, "Water Quality and Water Quality Problems, Ventura County". This investigation was conducted and report prepared in accordance with provisions of Sections 229 and 230, Chapter 2, of Division 1 of the Water Code.

This report evaluates the quality of surface and ground water supplies with respect to prevailing and anticipated beneficial uses of water in the County. It discusses the feasibility of reclamation of water from sewage, and the probable effects of future development upon water quality.

Sea-water intrusion into the ground water basin in the vicinity of Port Hueneme and Point Mugu is one of the most serious water quality problems in Ventura County today. Other problems which will be intensified as the County grows and develops include the disposal of sewage and industrial wastes, and maintenance of favorable salt balance in the ground water basins.

Appendixes bound in Volume II of the report contain a wealth of analytical data used as a basis for the report. This data together with the results of the periodic and continuing surface and ground water monitoring programs currently carried on by the Department of Water Resources will constitute a firm foundation for planning the water quality aspects of future water development projects.

Very truly yours,

Harvey O. Banks

HARVEY O. BANKS
Director

ACKNOWLEDGMENTS

The voluntary and valuable cooperation received from the following organizations and individuals and their contribution of data for this report are acknowledged with thanks:

United States Geological Survey,
Water Quality and Surface Water Branches

United States Navy Construction Battalion, Port Hueneme

United States Navy Air Missile Test Center, Point Mugu

WATER QUALITY AND WATER QUALITY PROBLEMS
VENTURA COUNTY

CHAPTER I. INTRODUCTION

Water quality problems and their effects upon surface and ground water supplies are of particular significance to Ventura County. Results of a comprehensive investigation of historic and existing quality of surface and ground water supplies, and the past and potential sources of degradation and pollution are presented in this report. In addition, there are presented the results of studies respecting the effects of proposed plans of development upon the quality of waters in Ventura County. Feasibility of the reclamation of water from sewage and industrial waste to overcome existing water supply deficiencies is also discussed.

This report on the quality of water supplements a prior county-wide investigation of the water resources and water requirements in Ventura County undertaken in 1951 as a cooperative study between the State of California and the County of Ventura. Results of that investigation are published in State Water Resources Board Bulletin No. 12, entitled "Ventura County Investigation", dated October, 1953.

Authorization

This investigation was conducted, and report prepared in accordance with Sections 229 and 230, Chapter 2 of Division 1 of the Water Code. Section 229 is quoted as follows:

> "229. The department, either independently or in cooperation with any person or county, state, federal, or other agency, to the extent that funds are allocated therefor, shall investigate conditions of the quality of all waters within the State, including saline waters, coastal and inland, as related to all sources of pollution of whatever nature

and shall report thereon to the Legislature and to the appropriate regional water pollution control board annually, and may recommend any steps which might be taken to improve or protect the quality of such waters."

Section 230 reads as follows:

"The department, either independently or in cooperation with any person or any county, state, federal, or other agency, to the extent funds are allocated therefor, shall conduct surveys and investigations relating to the reclamation of water from sewage or industrial wastes for beneficial purposes, including but not limited to, the determination of quantities of such water presently wasted, and possibilities of use of such water for recharge of underground storage or for agriculture or industrial uses; and shall report to the Legislature and the appropriate regional water pollution control board thereon annually."

Statement of Problem

Water, in its eternal movement from the mountains to the ocean, dissolves minerals from the rocks and soils with which it comes in contact. Upon the nature of the soils and the amount of salts dissolved depends the character and quality of the native water of an area. As the result of consumptive use of water by agricultural crops and native vegetation, and waste disposals of domestic and industrial origin, the concentration of mineral salts in water is increased and its quality deteriorates.

In parts of Ventura County, the 'undeteriorated" water supplies, both surface and in the principal water-bearing deposits, contain relatively high concentrations of total dissolved solids, sulfate, total hardness, and boron. Seepage of poor quality waters from older semipermeable formations, oil brine disposal, citrus packing plant wastes, and other wastes, have contributed additional salts to the water supplies. In the Oxnard Plain Basin, progressive lowering of piezometric levels in the confined aquifers to below sea level has resulted in sea-water intrusion.

Related Investigations and Reports

The following listed published and unpublished reports were reviewed during the investigation, and certain information and data presented therein were used in the preparation of this report. Reference is made to these reports in the text by superscript figures in parentheses.

Scope of Investigation and Report

Field and office work for this investigation was initiated in the fall of 1951, and continued into 1958. In the course of the field investigation, available analyses of surface and ground waters were collected and compiled. Additional samples of surface waters collected during varying conditions and rates of flow, were analyzed in order to determine relationships between quality and discharge. Sufficient wells were sampled to insure comprehensive areal water quality coverage of each of the ground water basins. In certain areas, particularly in the vicinity of Port Hueneme, wells were sampled periodically in an effort to determine quality trends.

In all, a total of 1,840 partial and 1,584 complete analyses of ground waters and 439 partial and 566 complete analyses of surface waters were made. These analyses were made in the Department of Water Resources laboratories. In addition, in excess of 600 complete mineral analyses of surface and ground water supplies, dating back to 1927, were obtained from Fruit Grower's Laboratory Incorporated, United Water Conservation District, Ventura Farm Advisor, and Division of Water Resources Bulletin No. 46A[2].

All available data concerning sources of deterioration of water supplies were compiled. Available analyses of sewage were collected from agencies disposing of wastes to the Pacific Ocean. Reports concerning possible pollution resulting from sewage and industrial waste discharges were reviewed and pertinent data abstracted. A brief investigation was made to ascertain the location of certain of the major waste discharges and conditions of disposal. In some instances, studies were made to determine if discharges were causing pollution or deterioration of surface or ground water supplies.

Pertinent reports respecting the reclamation of water from sewage were reviewed. Studies were made to determine the quality, economic

feasibility, and potential sites for beneficial use of water which could be reclaimed from this source.

As previously stated, this report is a companion investigation to Bulletin No. 12[11] of the State Water Resources Board. Therefore, the extensive studies of geology and hydrology which were prepared for and presented in that Bulletin, were utilized in the preparation of this report. Also, information pertinent to the interpretation of water quality has been abstracted therefrom.

Results of the investigation of water quality and water quality problems in Ventura County are presented in this report in the ensuing eight chapters. Chapter II contains information pertinent to this investigation which has been abstracted from Bulletin No. 12. Chapter III, "Water Utilization", cites the various beneficial uses of water in Ventura County and presents data to indicate the magnitude of the major uses. In Chapter IV, entitled "Water Quality Criteria", there are presented water quality criteria for each major prevailing beneficial use and a short discussion respecting each of the principal constituents found in water.

In Chapter V, entitled "Water Quality", there is presented a detailed discussion of the historic and present quality of the ground and surface waters in Ventura County as well as a discussion of the prospective quality of potential sources of imported supplies.

In Chapter VI, entitled "Water Quality Problems", there is presented a brief discussion of prevailing natural sources of deterioration in Ventura County and discussion of deterioration as a result of development, including the effects of industrial waste discharges, overdraft conditions, sewage disposals, and irrigation return. In addition, aspects of basin salt balance under present conditions are discussed. In Chapter VII, entitled "Reclamation of Water from Sewage", current water reclamation projects are reviewed and the results of studies to determine the feasibility of reclamation of sewage presently disposed to the Pacific Ocean are discussed.

In Chapter VIII, entitled "Water Quality Aspects of Water Resources Development", the effects of several of the proposed plans for water supply development in Ventura County are discussed. This includes proposals for the further development of existing supplies and the estimated effect of the importation of supplemental water from the Colorado River and from Northern California on the quality of waters in Ventura County. Chapter IX, entitled "Conclusions and Recommendations", summarizes the conclusions presented in the previous chapters and the actions recommended as a result of these studies of water quality and water quality problems in Ventura County.

In addition to the text there are eight appendixes containing supporting data. These data include mineral analyses of surface and ground waters, mineral and sanitary analyses of effluents from sewage treatment plants, and a cross index of State well numbers to Ventura County well numbers. Also included is a paper by Dr. Lloyd D. Doneen, entitled "Evaluating the Quality of Irrigation Water in Ventura County". These appendixes are bound separately in Volume II.

Description of Area

Ventura County forms a part of the South Coastal Area of California. It is bounded by Santa Barbara County on the west, Los Angeles County on the east and south, Kern County on the north, and the Pacific Ocean on the southwest as shown on Plate 1, "Area of Investigation". The area of the County, excluding Anacapa and San Nicolas Islands, which are a part of Ventura County, is 1,857 square miles. The area of investigation includes all of the mainland portion of Ventura County except the Cuyama River watershed.

The County is characterized by rugged mountainous terrain in

the northern portion and lower mountains and alluvial valleys in the central and southern portion. Numerous ridges in these mountains extend to elevations in excess of 6,000 feet, attaining a maximum elevation of 8,826 feet at Mt. Pinos, near the northern boundary of the County.

Drainage Systems

Ventura County is drained by four principal stream systems, formed by the Ventura, Santa Clara, and Cuyama Rivers, and Calleguas Creek. With the exception of the Cuyama River, these streams discharge into the ocean along the coastal front, forming the southwesterly boundary. The headwaters of the Cuyama River rise in the northwesterly portion of the County and drain into the ocean through the Santa Maria River. The Cuyama watershed and other minor areas in the westerly, northerly, and southerly portion of the County which drain into Santa Barbara, Kern, and Los Angeles Counties, except for that portion of the Malibu Creek drainage area which lies within Ventura County, are not covered in this report. In addition to the streams mentioned above, there are several minor watercourses and drainage channels which drain the southwesterly portion of the County and discharge into the ocean.

Climate

The mediterranean type of climate, typical of the southern coastal portion of California, prevails in Ventura County, with proximity to the ocean providing a moderating effect on climatic conditions throughout the developed area. A long, dry, warm summer season is followed by a shorter wet winter period accompanied by cooler temperatures. In excess of 80 per cent of the mean seasonal precipitation occurs during the months of December through March. Precipitation occurs generally in the form of rainfall, except in the mountainous regions where there is some snowfall in most years. Fog is prevalent along

the coast during portions of each year.

Temperature extremes generally increase with elevation and distance from the coast. The mean annual temperature at Oxnard is somewhat less than 60 degrees Fahrenheit. The cities of Ojai, Ventura, Santa Paula and Moorpark have mean annual temperatures of 60 degrees or slightly above. The growing season is long and generally decreases with elevation and distance from the coast. Killing frosts are rare on the coastal plain of the Santa Clara River valley. Portions of this area are producing as many as three crops per year.

Soils

In general, the soils in Ventura County may be divided into three groups: (1) residual soils, which have been developed in place from the disintegration and weathering of consolidated rocks, both of sedimentary and basic igneous origin; (2) old valley and coastal plain soils, which are derived from elevated, unconsolidated, water-laid deposits which have undergone marked changes since their deposition; and (3) recent alluvial soils, which are derived from sediments that have undergone little or no change since their deposition. These soils have their origin in a variety of materials, including shale, sandstone, conglomerate, basic igneous rocks, and old valley-fill deposits.

Residual soils are identified with hill and mountain areas and comprise a relatively small area of the county. They are found principally in the rolling hills and ridges at the perimeter of the interior valleys. Soil textures vary from medium to heavy and soil depths are generally shallow. Drainage is generally good, and moisture retention adequate, except where underlying bedrock is near the surface.

Soils of old valley fill and coastal plain groups occur both on hill and rolling lands, and on marine or stream terraces. These soils have

medium texture, are friable, and are well suited to irrigated agriculture. Subsoils are somewhat more compact and heavier in texture, with local tendencies to form a hardpan. Surface drainage is good but subsurface drainage is, in some cases, retarded by the heavy compact nature of the subsoil.

Topography, identified with the recent alluvial soils, is smooth and gently sloping. The group covers nearly the entire coastal plain of the Santa Clara River valley. Depth of soil is usually good, with textures grading from light to very heavy. The soils of this group have the common characteristic of stratification in the subsoil. On alluvial fans, both surface and internal drainage is very good. However, in some of the lower valleys, where the soil is quite heavy, drainage is poor, as in the southerly portion of the coastal plain and extending northerly therefrom toward Camarillo. An extensive drainage sytem has been constructed in this area to alleviate this problem.

Population

The 1950 Federal census reported the population of Ventura County to be 114,647, as compared to the 1940 population of 69,685. The increase during this period was about 65 per cent of the 1940 total. Estimates made by Planning Research Corporation indicate that the total county population was greater than 160,000 in 1957. The City of Oxnard, which ranked third in population in 1940, was first in 1958, with a population of 21,567 and 34,326, respectively, according to a 1958 special census. The estimated 1957 population of other incorporated cities in order of their magnitude was: Ventura, 28,300; Santa Paula, 12,370; Fillmore, 4,810; Port Hueneme, 8,750; and Ojai, 4,060.

Definitions

Terms, as used in this report, are defined as follows:

Aquifer - A formation or structure sufficiently permeable to yield water to wells or springs.

Confined Ground Water - A body of ground water overlain by materials sufficiently impervious to sever free hydraulic connection with overlying water and moving under pressure caused by the elevation at the intake area.

Contamination - As defined in Section 13005 of the Water Code, "Contamination means an impairment of the quality of the waters of the State by sewage or industrial waste to a degree which creates an actual hazard to public health through poisoning or through the spread of disease. . ." Jurisdiction over matters regarding contamination rests with the State Department of Health and local health officers.

Degradation - Any impairment in the quality of water due to causes other than disposal of sewage and industrial waste.

Free or Unconfined Water - This generally refers to a body of ground water in the zone of saturation that is not confined beneath an impervious formation.

Ground Water Overdraft - The quantity of ground water withdrawn from a ground water basin in excess of safe ground water yield.

Native Water - This term, when used with respect to quality of water, signifies the quality of the waters prior to the development of the area by man. As a practical matter, however, it is usually

used to signify the quality found at the time of the first mineral analyses of the water in areas where there are no evidences of pollution or deterioration.

Pollution - As defined in Section 13005 of the Water Code, "Pollution means an impairment of the quality of the waters of the State by sewage or industrial waste to a degree which does not create an actual hazard to the public health but which does adversely and unreasonably affect such waters for domestic, industrial, agricultural, navigational, recreational or other beneficial use . . ." Regional water pollution control boards are responsible for prevention and abatement of pollution as defined in this section.

However, the Attorney General has stated that the term "pollution" as used in Section 229 of the Water Code, which relates to investigations of water quality by the Department of Water Resources, is general in nature. Thus, with respect to this study, it encompasses all types of water quality deterioration, including sea-water intrusion and other types of degradation.

Quality of Water - This refers to those characteristics of water affecting its suitability for beneficial uses.

Refuse - Combustible and/or noncombustible organic and/or inorganic waste material (excepting sewage or industrial waste) originating in residential, commercial, or industrial areas.

Safe Ground Water Yield - The maximum rate of extraction of water from a ground water basin which, if continued over an indefinitely long period of years, would result in maintenance of certain desirable fixed conditions. Commonly, safe ground water yield is determined by one or more of the following conditions:

1. Mean annual extraction of water from the ground water basin

does not exceed mean annual replenishment to the ground water body.

2. Water levels are not lowered so as to cause harmful impairment of the quality of the ground water by intrusion of any other water of undesirable quality, or by accumulation and concentration of degradants or pollutants.

3. Ground water levels are not so lowered as to imperil the economy of ground water use by excessive costs of pumping from the ground water body, or by exclusion of users from that source of supply.

4. Prior rights of others in adjacent ground water basins are not interfered with.

Semiperched Ground Water - A ground water body, usually unconfined, lying above the main body of ground water and partially separated therefrom by unsaturated rock.

CHAPTER II. WATER SUPPLY

The quality of surface water is related to the geology of the tributary watershed and the frequency, intensity, and magnitude of precipitation. Likewise ground water quality is related to the sources of recharge and the geologic formations which form the ground water basins. This chapter presents a summary of the geology and hydrology of Ventura County with emphasis on the occurrence and movement of ground water in the principal ground water basins. Information set forth herein is based on detailed studies published in Bulletin 12 of the State Water Resources Board. (11)

Surface Water Supplies

The principal sources of water supply to Ventura County are direct precipitation on the valley floor and runoff from tributary drainage areas. However, a small amount of water imported from Los Angeles County and relatively minor quantities of water released from the Los Angeles aqueduct in the upper reaches of the Santa Clara River watershed have contributed to the supply. There is no record of export of water from Ventura County.

Precipitation.

Precipitation in Ventura County occurs primarily as rainfall, although light snowfall is not uncommon in the higher mountains in the northern portion of the County. The mean seasonal depth of precipitation varies from about 32 inches in the Topatopa Mountains to about 12 inches in the vicinity of Point Mugu.

Precipitation in the county exhibits extreme monthly and seasonal

variation. The seasonal variation at Ojai, which is similar to the variation at other stations within the county, is shown on Plate 3, entitled "Recorded Seasonal Precipitation at Ojai". The apparent cyclic nature of the occurrence of the precipitation at this station is shown on Plate 4 entitled, "Accumulated Departure from Mean Seasonal Precipitation at Ojai". Approximately 80 per cent of the seasonal precipitation occurs during the 4-month period December through March, although it is not unusual for one or more of these months to be extremely dry in any given season.

Runoff

Runoff flowing in streams in Ventura County is derived primarily from rainfall and exhibits similar monthly and seasonal variations. Absence of snowpack in the tributary watersheds causes flow in all streams to diminish rapidly at the conclusion of the winter precipitation season, although some summer flow is maintained by springs in the upper reaches of the more productive watersheds. Seasonal natural runoff in the principal streams of the county has varied from a maximum in excess of 400 per cent of the mean to a minimum of less than 5 per cent. Following a severe storm, discharge in the larger streams has been known to increase from practically no flow to a rate of thousands of cubic feet per second in a few hours time. Seasonal variations in the runoff of Sespe Creek near Fillmore are presented on Plate 5 entitled, "Estimated Seasonal Natural Runoff of Sespe Creek near Fillmore", and the cyclic nature of the occurrence of runoff at this station is shown on Plate 6 entitled, "Accumulated Departure from Mean Seasonal Natural Runoff of Sespe Creek near Fillmore".

Major drainage systems in Ventura County which are included in this report are: Ventura River, Santa Clara River, and Calleguas Creek. In addition, a portion of the Malibu Creek system lies within Ventura County. Runoff in each of these systems is briefly discussed below. The locations of the various streams in each of the drainage systems in Ventura County are delineated on Plates 7A, B & C, entitled "Location of Surface and Drainage Water Sampling Stations".

Tributary runoff is disposed through percolation to ground water storage in absorptive stream channels and artificial spreading grounds, evaporation, consumptive use of native vegetation, diversions to meet the requirements of irrigated agriculture and urban development, and discharge to the ocean.

Ventura River System. Ventura River, which originates in the Santa Ynez and Topatopa Mountains and drains an area of approximately 226 square miles, flows in a southerly direction discharging to the Pacific Ocean at the City of Ventura. The principal tributaries of Ventura River are Matilija, Coyote, and San Antonio Creeks, and Canada Larga.

According to State Water Resources Board Bulletin No. 12[11], the discharge at Station No. 42-5.7, Ventura River near Ventura, ranged from a maximum of 256,000 acre-feet to a minimum of zero, averaging 59,000 acre-feet, for the period 1936-37 through 1950-51. Average values of runoff in the Ventura River and certain of its tributaries are presented in Table 1 entitled, "Maximum, Minimum and Average Measured and Estimated Seasonal Runoff at Key Stream Gaging Stations in or near Ventura County, 1936-37 through 1950-51". The location of each of these stations is delineated on Plate 7A entitled "Location of Surface and Drainage Water Sampling Stations, 1958".

TABLE 1

MAXIMUM, MINIMUM AND AVERAGE MEASURED AND ESTIMATED SEASONAL RUNOFF AT KEY STREAM GAGING STATIONS IN OR NEAR VENTURA COUNTY 1936-37 THROUGH 1950-51

Stream and Station	Stream mile location number	Drainage area, in square miles	Annual Runoff in acre feet		
			Maximum	Minimum	Average
Matilija Creek at Matilija	42-15.6-0.2	55	125,280	1,540	29,420
North Fork Matilija Creek at Matilija	42-15.6a-0.5	15.5	31,290	590	8,000
Coyote Creek near Ventura	42-6.0-0.3	41	50,890	50	11,220
Ventura River near Ventura	42-5.7	187	256,300	0	59,040
Santa Clara River near Saugus	43-45.5	410	49,770	220	15,300
Santa Clara River 1/2-mile west of county line	43-37.3	644	86,110	4,280	33,530
Piru Creek near Piru	43-31.8-3.2	432	226,300	2,410	57,270
Hopper Creek near Piru	43-28.9-1.0	23	15,400	140	4,430
Sespe Creek near Fillmore	43-21.5-6.0	254	371,700	1,290	90,160
Santa Paula Creek near Santa Paula	43-15.9-3.8	40	57,680	990	17,040
Arroyo Simi near Simi	44-12.2-5.8-8.5	75	7,150	0	1,120
Arroyo Las Posas near Moorpark	44-12.2-5.8-2.7	118	9,350	0	1,500
Malibu Creek at Crater Camp near Calabasas	45-4.3	103	73,220	60	15,620

Santa Clara River System. The Santa Clara River drains 1,064 square miles below the Ventura-Los Angeles County line and 627 square miles above the County line or a total of 1,691 square miles. The river originates in the Sierra Pelona and San Gabriel Mountains in Los Angeles County and flows in a westerly direction to enter the Pacific Ocean just south of the City of Ventura. The principal tributaries in Ventura County are Piru, Hopper, Sespe and Santa Paula Creeks from the north and Salt Creek from the south. Piru and Sespe Creeks, which drain 432 and 254 square miles, respectively, are the largest of these tributaries.

It was estimated in State Water Resources Board Bulletin No. 12 that the 15-year average seasonal natural runoff at Station No. 43-37.3, known as Santa Clara River one-half mile west of the Los Angeles-Ventura County line, was 33,530 acre-feet. During this period the maximum flow recorded was 86,110 acre-feet and the minimum flow recorded was 4,280 acre-feet. Average annual values of runoff during the period 1936-37 through 1950-51 at selected stations on the Santa Clara River and its tributaries are presented in Table 1. The location of the gaging stations is delineated on Plate 7B.

Historically, imported water has entered the Santa Clara River drainage area through release from the Los Angeles aqueduct or as the result of spill from Bouquet Canyon Reservoir on the aqueduct system. A total of 60,900 acre-feet of water was discharged to Santa Clara River from these sources during the period 1936-37 through 1950-51. While this release contributed to water supply to Ventura County the quantitative effect on the long time average supply is relatively small.

Calleguas Creek System. The Calleguas Creek system drains 331 square miles. Arroyo Simi and Tapo Creeks, the headwaters of this system, originate in the Santa Susanna and Santa Monica Mountains. Arroyo Simi, rising near the Los Angeles-Ventura County line east of Santa Susanna, flows in a westerly direction through Simi Valley to a short distance southwest of Moorpark, at which point the stream name changes to Arroyo Las Posas. The stream then continues in a westerly direction until near Somis, where it turns to the south, with a second change of name to Arroyo Calleguas. Southeast of Camarillo the stream is called Calleguas Creek, and flows in a southwesterly direction toward Mugu Lagoon and the Pacific Ocean.

The runoff in Calleguas Creek System is relatively minor. The seasonal flow in Arroyo Las Posas near Moorpark has varied from a minimum of zero (for several seasons) to a maximum of approximately 9,000 acre-feet during the period 1936-37 to 1950-51. The runoff averaged 1,500 acre-feet per year for the 15-year period. The locations of gaging stations on the Calleguas Creek System are delineated on Plate 7C.

Malibu Creek System. The southerly slopes of the Santa Monica Mountains within Ventura County are drained by Los Virgenes and Triunfo Creeks, tributaries of Malibu Creek, together with several minor streams discharging directly into the ocean. However, runoff from these streams is minor in quantity and has little or no effect on the water supply situation in Ventura County.

Surface Reservoir Storage

Nine reservoirs in Ventura County, utilized for stream flow regulation, are sufficiently large to be subject to the jurisdiction of the State of California. In addition, there are three reservoirs in the County which are used to impound waste from oil field operations. Information concerning these latter structures is presented in the discussion on oil industry wastes in Chapter VI.

The principal conservation reservoirs in Ventura County are created by Matilija and Santa Felicia Dams, the locations of which are delineated on Plates 7A and B. Matilija Dam is a concrete arch structure, 163 feet in height forming a reservoir with storage capacity of about 7,000 acre-feet. It was constructed in 1948 by the Ventura County Flood Control District. Santa Felicia Dam on Piru Creek, constructed by the United Water Conservation District, was completed in 1955. It is an earthfill type dam, creating a reservoir with maximum storage capacity of 100,000 acre-feet.

In addition to existing dams, the United States Department of Interior, Bureau of Reclamation has initiated construction of Casitas Dam on Coyote Creek of the Ventura River drainage area as shown on Plate 7A. An earthfill dam will provide a reservoir with a capacity of 250,000 acre-feet which will impound waters diverted from the Ventura River during periods of high runoff in addition to runoff from the Coyote Creek watershed.

Surface Diversions

Utilization of surface waters in Ventura County is limited to a relatively few users along the Ventura and Santa Clara Rivers and their

tributaries. Along the Santa Clara River system, the users divert the uncontrolled surface flow including rising water, of Piru, Sespe, and Santa Paula Creeks. Supplies from these sources are not dependable in quantity, and in some years disappear completely. Many users of surface water supplies are also equipped to pump supplemental ground water.

The City of Ventura is the largest user of surface waters along the Ventura River, and has pumped ground water to supplement this supply when necessary. Above the City's diversion near Foster Park, several gravity diversions supply water to agricultural users and small urban entities adjacent to the river.

A list of the major users, sources of supply, locations of diversions, and other pertinent data is presented in Table 2 entitled "Major Diversions of Surface Water in Ventura County".

TABLE 2

MAJOR DIVERSIONS OF SURFACE WATER IN VENTURA COUNTY

User	Source of supply	General location of lands served	Point of diversion	Estimated present average seasonal diversion, in acre-feet	Principal use
Ventura County Flood Control District	Matilija Creek	Ojai Basin	Matilija Reservoir	1,048	Ground water replenishment
Miscellaneous users above Meiners Oaks[a]	Ventura River	Upper Ventura River Basin	Between confluence of Matilija and North Fork of Matilija Creeks and Meiners Oaks	1,100	Irrigation
City of Ventura	Ventura River	City of Ventura	At Foster Park	5,700[b]	Municipal
Waring Bros. Irrigation Service	Piru Creek	Piru Basin	One-half mile above railroad Bridge at Piru	800	Irrigation
United Water Conservation District (Piru Spreading Grounds)	Piru Creek	Piru Basin	At Piru	5,097	Ground water replenishment
Fillmore Irrigation Company	Sespe Creek	Fillmore Basin	One mile above U.S.G.S. gaging station near Fillmore	4,600	Irrigation
Farmer's Irrigation Company	Santa Clara River	Santa Paula and Mound Basins	One mile above Santa Paula Bridge	1,300	Irrigation
Miscellaneous agricultural users above Santa Paula Water Works diversion	Santa Paula Creek	Santa Paula Basin	----	300	Irrigation
Santa Paula Water Works, Ltd.	Santa Paula Creek	City of Santa Paula	At U.S.G.S. gaging station near Santa Paula	2,800	Municipal
Santa Clara Water and Irrigation Company	Santa Clara River	Oxnard Plain Basin	Near Saticoy	700	Irrigation
United Water Conservation District (Saticoy Spreading Grounds)	Santa Clara River	Oxnard Forebay Basin	Near Saticoy	10,300	Ground water replenishment
United Water Conservation District (El Rio Spreading Grounds)	Santa Clara River	Oxnard Plain	Near Saticoy	7,330	Ground water replenishment
Ventura County Flood Control District	Runkle Canyon Creek	Simi Valley	Two miles southwest of Santa Susana	Not measured	Ground water replenishment

b. Estimated present water requirement of City of Ventura. City would divert this amount if available.

Ground Water Supplies

Regulation of the available water supplies of Ventura County is accomplished principally through utilization of the storage capacity in underlying ground water reservoirs. Usable ground water supplies are found in the valleys and in some hill areas in the southern part of the county. These supplies occur principally in alluvium and unconsolidated sediments, and to a lesser extent in consolidated and fractured rock of sedimentary and volcanic origin. Underground water supplies are replenished by percolation of surface waters, both in natural absorptive channels and in artificial spreading grounds; by deep penetration of precipitation and the unconsumed portion of applied irrigation water; and by subsurface inflow from adjacent ground water basins. Disposal of ground water supplies is effected by pumped extractions, discharge as rising water, consumptive use by native vegetation in areas subject to high ground water levels, and subsurface outflow.

As an introduction to the discussion of ground water geology and hydrology in Ventura County there is presented a discussion of geologic formations. Following this, there is a brief discussion of the geologic and hydrologic characteristics of the individual ground water basins found in each of the drainage systems in Ventura County. These data are summarized in Table 3, "Principal Geologic and Hydrologic Aspects of Ground Water Basins in Ventura County"; the areal geology of Ventura County is delineated on Plate 8. Contours depicting the ground water level in the spring of 1957 are shown on Plate 2.

Geologic Formations

Rocks found in Ventura County consist of marine and nonmarine sediments, ranging in age from Cretaceous to Recent, and volcanics of Miocene age. The sediments and volcanics are underlain by a pre-Cretaceous basement complex composed of igneous and metamorphic rocks. These formations are probably underlain by sedimentary rocks of Jurassic age in some areas. From the standpoint of water supply, geologic formations may be separated into two categories, nonwater-bearing formations and water-bearing formations. Formations included among each of these two categories are discussed in the following paragraphs.

Nonwater-Bearing Series. Nonwater-bearing deposits in Ventura County include the basement complex, sediments of Cretaceous and Tertiary age and volcanics of Miocene age. Outcrops of these deposits are delineated on Plate 8. Although the sediments of the nonwater-bearing series are generally incapable of producing a dependable supply there are domestic wells throughout Ventura County which extract limited amounts of water from these deposits, and a few wells which yield large amounts of water.

Water-Bearing Series. The water-bearing deposits in Ventura County include lower Pleistocene age sediments, upper Pleistocene sediments and Recent alluvium.

The deposits of lower Pleistocene age consist of the Santa Barbara and the San Pedro formations. The Santa Barbara formation, which ranges from upper Pleistocene to lower Pleistocene in age, contains mudstone, shale, and minor sandstone beds. Near the top of the Santa Barbara formation a deposit of sand and gravel forms the Grimes Canyon aquifer, which is an important source of ground water in Los Posas Basin. The lower Pleistocene San Pedro

formation consists of marine and continental sands, gravels and clays that range up to 4,000 feet in thickness, and supply water to wells in the Santa Clara River Valley, Pleasant Valley, and Las Posas Basin areas. At the base of the San Pedro formation is an important aquifer, known as the Fox Canyon aquifer, which consists of 100 to 400 feet of sands and gravels.

Upper Pleistocene silts, sands, gravels, and clays overlay the San Pedro formation. In the Oxnard Plain area these sediments extend from the top of the San Pedro formation to within about 20 to 50 feet of the surface. The main aquifer in the Oxnard Plain Basin is a stream-deposited gravel within these upper Pleistocene sediments, termed the Oxnard aquifer. Some water is also obtained from lenticular upper Pleistocene gravels in the Pleasant Valley area.

Deposits of Recent alluvium in the region are usually less than 50 to 60 feet thick and consist of sands, gravels, and clays. As the Recent alluvium is very shallow, most wells obtain water from older formations.

Ground Water Basins, Ventura River System

Ground water basins within the Ventura River system include the Upper Ojai, Ojai, Upper Ventura River and Lower Ventura River Basins. The location of these basins is delineated on Plate 2 and a summary of geologic and hydrologic information is set forth in Table 3. In general, the basins of this system are small and have limited storage capacity. For this reason, they are quickly recharged during wet periods and rapidly depleted during periods of drought. The lands of this system not included within the indicated limits of ground water basins are principally underlain by formations of low permeability which do not yield water readily to wells. However,

in these areas, some water is obtained from fractures and pervious zones within consolidated Tertiary deposits.

Upper Ojai Basin. Upper Ojai Basin is situated in the northwesterly part of the Ventura River system. The principal water-bearing deposits are found in the Pleistocene and Recent alluvium that covers the floor of the Basin to an average depth of approximately 60 feet. The alluvium is flanked by the folded and faulted Pico, Santa Margarita, Modelo, Rincon, Vaqueros and Sespe formations as shown on Plate 8. Fractures in these Tertiary formations contain some ground water and many small springs are supplied from fractures in these rocks.

In the Upper Ojai Basin, ground water moves westerly into Lyon Canyon of the Ventura River drainage system as shown by contours of water levels on Plate 2. Consolidated Tertiary formations prevent any appreciable subsurface outflow of ground water from the Upper Ojai Basin into Ojai Basin.

Ojai Basin. Ojai Basin, the principal ground water basin in the Ventura River drainage system is a down faulted and folded area that has been filled with Recent and Pleistocene stream alluvium to depths which range up to 700 feet in thickness. The alluvium rests on and is flanked by Tertiary formations. Although some ground water is contained in fractures derived from the flanking Tertiary formations, the major portion of the readily available supply is contained in the alluvial floor of the basin. Water diverted from Matilija Reservoir into the Ojai spreading grounds serves as a partial source of recharge to the ground water reservoir.

Ground water in the Ojai Basin moves south and west and converges on San Antonio Creek at its outlet from Ojai Valley. However, during periods

of low water levels the water table slope has been reversed to form a depression or trough in the vicinity of Ojai as indicated by ground water contours on Plate 2. During periods of high water levels, some wells located in the southwestern part of the basin exhibit conditions of artesian flow, suggesting the occurrence of locally confining conditions.

At the west end of Ojai Valley available evidence suggests that subsurface outflow is blocked by nonwater-bearing materials of the Sespe formation. This, and the fact that bedrock is exposed in San Antonio Creek indicate that subsurface outflow from Ojai Basin into Upper Ventura River Basin is probably insignificant.

Upper Ventura River Basin. The Recent alluvium is the principal water-bearing deposit found in the Upper Ventura River Basin. This basin includes the Upper Ventura River Valley, the Coyote Creek drainage area, and that part of the San Antonio Creek drainage area downstream from Ojai Valley. In the Ventura River Valley the depth of this alluvium ranges from 60 to 100 feet, while in the smaller San Antonio and Coyote Creeks the fill is thinner, ranging from 5 to 30 feet in depth. These alluvial deposits rest on and are flanked by folded and faulted Tertiary formations. Most of the ground water in the basin is contained in the alluvial deposits, although some water is contained in fractures in older formations. Free ground water conditions generally prevail throughout the basin, although there are some localized bodies of confined water. Subsurface flow to Lower Ventura River Basin occurs around the east end of a subsurface barrier built by the City of Ventura near Foster Park.

Lower Ventura River Basin. Alluvial deposits that range from 60 to 100 feet thick in the floor of the Ventura River Valley are the important aquifers in this basin. The alluvium of the basin is generally underlain by nonwater-bearing Tertiary formations. The water-bearing San Pedro formation flanks and underlies the alluvium at the mouth of the Ventura River, although this aquifer appears to be hydraulically isolated from the alluvium by impermeable formations, and is considered to be part of the Mound Basin. Utilization of ground water from the Lower Ventura River Basin has been negligible since 1926, when most wells were abandoned because of poor quality.

Ground Water Basins, Santa Clara River System.

Ground water basins in this system comprise Piru, Fillmore, Santa Paula, Mound, Oxnard Forebay, Oxnard Plain, and Pleasant Valley Basins. Collectively, they are the most productive basins in Ventura County. The location of these basins is delineated on Plate 2, and the principal geologic and hydrologic characteristics of these basins are given in Table 3. Direction of movement of ground water in the spring of 1957, as indicated by lines of equal elevation of ground water, is shown on Plate 2.

Piru Basin. Piru Basin is the easternmost basin lying entirely within Ventura County. The principal water-bearing deposits of upper Pleistocene and Recent alluvium and underlying Pleistocene San Pedro formation coincide axially with the Santa Clara River syncline, and the San Pedro formation has been folded into the syncline. Southeast of Piru the synclinal axis has been folded upward, causing the San Pedro formation to be truncated by erosion. In addition, Tertiary formations have been moved over the younger San Pedro

formation by thrusting along the San Cayetano and Oakridge faults. These older formations are essentially nonwater-bearing but may contribute some water of poor quality to the main aquifers.

The thickness of the alluvial deposits rangesfrom 85 to 200 feet, whereas the San Pedro formation may attain a thickness approaching 4,000 feet. At the eastern boundary of the basin, near Blue Cut, the alluvium covering the nonwater-bearing deposits is thin, with the result that subsurface inflow is negligible. At the western boundary of Piru Basin a constriction impedes the flow of ground water and results in rising water in Santa Clara River.

Fillmore Basin. The principal water-bearing deposits in Fillmore Basin are the alluvium of Pleistocene to Recent age, up to 250 feet in thickness, and the San Pedro formation, which may have a thickness as great as 4,000 feet. East of Santa Paula, the cross sectional area of the San Pedro formation has been reduced by warping of the Santa Clara River syncline. This restriction forms the western boundary of the basin, through which a minor amount of subsurface outflow occurs. On the south side of the basin, in the Bardsdale area, the alluvium overlies the shelf of nonwater-bearing rocks which have been thrust upward by the Oakridge fault. The alluvium overlying this shelf is up to 180 feet thick.

Historically, the alluvium has been substantially dewatered in certain areas along the north and south sides of Fillmore Basin, with the result that several wells have gone dry. However, in most areas, deepening of wells into the underlying San Pedro formation would probably have alleviated the difficulty. An exception to this general situation exists in the

southerly portion of Fillmore Basin, south of the Oakridge fault, where the alluvium is underlain by relatively nonwater-bearing Tertiary deposits.

Santa Paula Basin. The alluvium in the Santa Paula Basin ranges up to 200 feet in thickness, while the underlying San Pedro formation is about 4,000 feet thick. In the northwestern part of the basin near Saticoy, deposits of yellow silty clay overlie the principal gravel zones in the alluvial deposits creating locally confined conditions. Underlying and flanking the San Pedro formation are semipermeable Tertiary deposits, which may yield water of poor quality to wells.

Ground water moves toward the west end of the basin, where movement is impeded by the Saticoy fault. Water levels are 50 to 100 feet higher on the upstream side of the fault than on the downstream side, indicating that this fault is an effective ground water barrier. Between Santa Paula and Mound Basins there is a relatively steep hydraulic gradient, which may be caused by a decrease in permeability in the underlying sediments or by some unknown faulting in the San Pedro formation.

Mound Basin. The San Pedro formation, which is the principal water-bearing deposit in the basin, is overlain by alluvium and underlain by Santa Barbara formation. The alluvial deposits, which range from upper Pleistocene to Recent in age, consist of yellow clay that has intercalated lenses of sand and gravel. The alluvium is underlain by 4,000 feet of gravels, sand, silts, and clays which make up the San Pedro formation. The upper 500 to 1,000 feet of the San Pedro formation consists of many permeable beds of sands and gravels that are discontinuous and extremely lenticular. These form the principal sources of ground water in this basin.

At the present time, there is insufficient evidence to indicate that sea water is intruding into the San Pedro formation. It is possible that the submarine extensions of the formations may be in hydraulic continuity with the ocean, and consequently, inflow of sea water or outflow of fresh water can occur. There is uncertainty as to the hydraulic continuity of the San Pedro formation between the Mound Basin and Oxnard Plain Basin, but it is possible that subsurface inflow to or outflow from the Oxnard Plain Basin may occur when water levels are favorable.

Oxnard Forebay Basin. Formations in this basin include Recent and upper Pleistocene alluvium underlain unconformably by the San Pedro formation and, in a small area, by the Santa Barbara formation.

Alluvium of Recent and upper Pleistocene age is the most important material in the Oxnard Forebay since it forms the ground water reservoir for most of the water used in Oxnard Plain Basin. The alluvium consists of up to about 400 feet of river deposited gravel, clay, and sand.

The Oxnard Forebay Basin is a free ground water basin in which there is hydraulic continuity between ground surface and the ground water table. The upper gravels are continuous with the Oxnard aquifer of Oxnard Plain Basin. The alluvium is underlain by permeable sands and gravels of the San Pedro formation, called the Fox Canyon member.

Ground water in the Oxnard Forebay Basin is the principal source of recharge to the Oxnard Plain Basin through the aquifers in the alluvium and the San Pedro formation. Outflow through the San Pedro formation into Mound Basin may occur at times in the area near Montalvo.

Oxnard Plain Basin. The principal water-bearing formations in the Oxnard Plain Basin are Recent and Pleistocene alluvial deposits, which range in thickness from 400 to 500 feet and the underlying San Pedro formation, the thickness of which ranges from about 600 feet in the south to almost 1,800 feet in the north of the basin. The Oxnard aquifer, of Recent and Pleistocene age, is the most important aquifer in the basin. It ranges from 75 to 200 feet in thickness and is confined by a layer of clay with interbedded lenses of sand and gravel up to 150 feet in thickness. The clay supports a semiperched water body, but slow infiltration through the cap probably contributes to the recharge of the Oxnard aquifer. Another aquifer is found in the southeastern part of the basin where a fairly continuous bed of gravel 70 feet thick is encountered at depths of about 400 feet near the base of the upper Pleistocene alluvium. The most important aquifer in the San Pedro formation is the Fox Canyon member, consisting of sands and gravels which range from 100 to 300 feet in thickness. These three aquifers are in hydraulic continuity with the ocean near Port Hueneme, or Point Mugu or both. Limited quantities of water are obtained from other permeable zones in the San Pedro formation and in the upper Pleistocene sediments.

Pleasant Valley Basin. The Recent and upper Pleistocene alluvium and the San Pedro and Santa Barbara formations are the principal sources of ground water in Pleasant Valley Basin. In the area north of the Camarillo fault and south of the Camarillo hills, the alluvium consists of about 400 feet of yellow and blue clays with lenticular water-bearing sands and gravels. South of the Camarillo fault, the alluvium consists mostly of clay with

irregularly interbedded sands and gravels, with a total thickness of 400 feet. The San Pedro formation underlies the entire basin, ranging in thickness from 400 to 1,500 feet, and has at its base the Fox Canyon member. The Fox Canyon member, ranging in thickness from 100 to 300 feet, is the most important aquifer in Pleasant Valley Basin. Underlying the San Pedro formation is the Santa Barbara formation, which varies from 50 to 900 feet in thickness. Only a few wells obtain water from this latter formation and, since the sediments are of a fine-grained nature, it has not been developed as an important aquifer. Adjacent to and underlying the southern part of the basin are volcanic rocks which yield water to wells from fractures and from gravels interbedded with volcanic flows.

Nearly all ground water bodies of this basin are confined, the exception being the Fox Canyon member, which is unconfined in a limited area near Somis. During periods of heavy draft, ground water moves toward the center of the basin, whereas when water levels are high, ground water moves in a southerly direction through the basin.

Ground Water Basins, Calleguas Creek System.

Ground water basins in the Calleguas Creek drainage system include Simi, East and West Las Posas, Conejo, Tierra Rejada, and Santa Rosa Basins. The remaining lands of the system are principally underlain by formations of low permeability, which do not yield water readily into wells. The location of these basins is delineated on Plate 2. Table 3 presents a summary of some of the characteristics of these basins. The direction of ground water movement, as evidenced by contours of ground water elevation for the spring of 1957, is shown on Plate 2.

Simi Basin. The principal water-bearing formation in Simi Valley is the Recent and Pleistocene alluvium consisting of sands, gravels, and clays, covering the floor of the valley to depths that range up to 730 feet. The clay content increases toward the west end of the basin causing localized conditions of confined ground water. Underlying the alluvium are semipermeable Tertiary formations which contain water in fractures and interstices. However, they do not yield large amounts of water to wells. In the Tapo Canyon area about 1,000 feet of water-bearing sands and gravels and some clays of the Santa Barbara formation have been folded into a tight syncline. This formation, the second most important source of ground water in Simi Valley, is separated from alluvium of Simi Valley by nonwater-bearing rocks as shown on Plate 8.

Subsurface outflow from this basin moves through the alluvium to Arroyo Simi where the alluvium appears to be only 60 to 100 feet deep and about 1,000 feet wide.

East Las Posas Basin. The principal aquifers in this basin are the alluvium and the San Pedro and Santa Barbara formations. The alluvium is Pleistocene to Recent in age and reaches a maximum thickness of 200 feet in the vicinity of Moorpark. The San Pedro formation in this basin consists of about 2,000 feet of gravel, sands, and clays, and contains two important aquifers, the Epworth gravels and the Fox Canyon member. The Epworth gravels, which consist of up to 2,000 feet of gravels, sands and silts and clay, are located near the top of the San Pedro formation. The Fox Canyon member, situated near the base of the San Pedro formation, is about 100 to 400 feet thick and consists of sands, gravels with interbedded clay and silt lenses. With the exception of these two aquifers, the San Pedro formation does not yield large amounts of water to wells. The underlying Santa Barbara formation is up to

2,000 feet thick and has at its top a coarse gravel member known as the Grimes Canyon aquifer. The thickness of this aquifer varies greatly, ranging from a few feet to 1,000 feet. The portion of the Santa Barbara formation underlying the Grimes Canyon aquifer has low permeability and yields little water to wells.

Subsurface inflow into the basin is limited to that coming from older rocks and minor amounts from Simi Valley through the alluvium. Subsurface outflow is to Pleasant Valley Basin.

West Las Posas Basin. West Las Posas Basin is geologically similar to East Las Posas Basin. The important aquifers of the basin are the Fox Canyon member of the San Pedro formation and the Grimes Canyon member of the Santa Barbara formation. The San Pedro formation is over 1,300 feet thick with the lowermost Fox Canyon member, consisting of sand and gravel, being 200 to 300 feet thick. In this basin, the Grimes Canyon member is up to 300 feet thick. Between the Grimes Canyon and Fox Canyon aquifers there is a bed of clay ranging up to 600 feet in thickness, which generally acts as an impermeable barrier between the two aquifers. There are places, however, where the clay has been eroded away at the base of the Fox Canyon aquifer and continuity exists between the aquifers. The alluvial deposits, 200 to 300 feet in thickness, that overlie the San Pedro formation consist of silts and clays similar to those in the San Pedro formation. These deposits yield minor amounts of water from sand and gravel lenses.

Folding of the formations underlying the alluvium has resulted in the Fox Canyon aquifer being exposed along the edges of the basin, and deeply buried in the middle. Ground water is confined in both the Fox

Canyon and Grimes Canyon aquifers except where they are exposed on the south slopes of the Oak Ridge and where they are folded in the Camarillo Hills. Subsurface outflow is to the Oxnard Plain Basin.

Conejo Basin. Conejo Basin differs from most of the other basins in Ventura County in that its boundaries coincide with the drainage divides. Geologic formations in the basins consist of alluvium and sedimentary and volcanic formations of Tertiary and older age. The alluvium is shallow, except at Newbury Park and Thousand Oaks, where it attains a thickness of about 60 feet. Although the formations underlying the alluvial deposits are folded and faulted, the geologic structure appears to have little effect on the occurrence and movement of ground water. Ground water is contained in the alluvium, in fractures and weathered portions of volcanic rocks and Modelo shales, and in pervious zones of the Modelo sandstones and Topanga formations.

Tierra Rejada Basin. This basin is underlain by water-bearing volcanic rocks about 2,000 feet thick. These rocks underlie the entire basin with the exception of a small area underlain by sedimentary formations of Tertiary age. Most of the water in the basin occurs as unconfined water in highly fractured volcanic rocks. Ground water moves toward the west end of the basin where subsurface outflow to Santa Rosa Basin is impeded by a north trending fault.

Santa Rosa Basin. The Santa Rosa Basin is covered with Recent and Pleistocene alluvium consisting of sands, gravels, and clays, ranging up to 200 feet in thickness. Underlying the alluvium is the San Pedro formation, which contains up to 200 feet of gravel, sand, silt, and clay. At the base

of this formation, in the western part of the basin, there is a sand and gravel bed which is about 100 feet thick and is probably the equivalent of the Fox Canyon member. On the south side of the basin the San Pedro formation is underlain by Tertiary volcanics. Some Tertiary sedimentary rocks also underlie and are adjacent to the basin. There is subsurface inflow from both Tierra Rejada and Conejo Basins, but the magnitude of the inflow cannot be estimated because of insufficient data. Subsurface outflow through the San Pedro formation is westward into Pleasant Valley.

Ground Water Basins, Malibu Creek System.

Russell and Hidden Valleys comprise the principal areas in the Malibu Creek drainage area in Ventura County where ground water is extracted. In these basins ground water is derived primarily from alluvial deposits although some water is also extracted from volcanic rocks and the Topanga and Modelo formations. Nearly all formations have low storage capacity and low specific yield.

TABLE 3

PRINCIPAL GEOLOGIC AND HYDROLOGIC ASPECTS
OF GROUND WATER BASINS IN VENTURA COUNTY

Ground water basin		Area in acres	Water-bearing formations	Principal aquifers	General direction of ground water movement within basin	Direction of underflow out of basin	Condition of occurrence of ground water
Number	Name						
			Ventura River System				
4-1	Upper Ojai	1,950	Recent and Pleistocene alluvium	Lenses of permeable sediments	Westerly and easterly[a]	Westerly as rising water to Lion Canyon Valley and easterly as rising water to Sisar Creek, thence to Santa Paula Basin	Unconfined
4-2	Ojai	6,040	Recent and Pleistocene alluvium	Lenses of permeable sediments	Westerly and southwesterly	Southwesterly as rising water to San Antonio Creek and Upper Ventura Basin	Essentially unconfined, locally semiconfined
4-3.02	Upper Ventura River	4,900	Recent and Pleistocene alluvium	Sand and gravel beds	Southerly	Southerly to Lower Ventura River Basin	Unconfined
			Santa Clara River System				
4-4.06	Piru	6,520	Recent and Pleistocene alluvium	Sand and gravel beds	Westerly	Westerly to Fillmore Basin	Unconfined
			San Pedro	Sand and gravel beds	Westerly	Westerly to Fillmore Basin	Unconfined
4-4.05	Fillmore	16,870	Recent and Pleistocene alluvium	Sand and gravel beds	Westerly	Westerly to Santa Paula Basin	Unconfined
			San Pedro	Sand and gravel beds	Westerly	Westerly to Santa Paula Basin	Unconfined
4-4.04	Santa Paula	13,520	Recent and Pleistocene alluvium	Lenses of permeable sediments	Westerly	Southwesterly to Oxnard Forebay Basin and westerly to Mound Basin	Essentially unconfined
			San Pedro	Lenses of permeable sediments	Westerly	Southwesterly to Oxnard Forebay Basin and westerly to Mound Basin	Essentially unconfined
4-4.03	Mound	12,300	San Pedro	Lenses of permeable sediments near top	Southwesterly	Southwesterly to the ocean	Confined

a. There is a ground water divide near the eastern end of the basin.
b. Simi Valley is essentially a valley of internal drainage, especially during periods of low water levels.

CHAPTER III. WATER UTILIZATION

In Ventura County, water is utilized for many beneficial uses, including irrigated agriculture, urban, recreational, and preservation and propagation of fish and wildlife. In addition, water is consumptively used by native vegetation, lost by evaporation from surface water bodies and impervious areas, and utilized as a vehicle for the disposal of wastes.

Irrigation Use

At the present time the greatest use of applied water in Ventura County is for the irrigation of crops. Data presented in State Water Resources Board Bulletin No. 12[11] indicate that the annual use in agriculture is approximately 160,000 acre-feet of water. The principal crops are citrus, avocados, beans, nuts, truck, and alfalfa. Minor crops include deciduous fruit, sugar beets, and irrigated pasture. Forecasts of the ultimate land use pattern in Ventura County indicate that the acreage devoted to irrigated agriculture will probably increase gradually for the next 10 or 15 years when water requirements will approximate 186,000 acre-feet annually. After that time, it is estimated that agricultural acreages will decrease and agricultural water requirements will decrease to roughly one-half of present values or approximately 80,000 acre-feet annually.

Urban Use

The urban uses of water include domestic, municipal, and industrial. Utilization of water for domestic and municipal purposes includes requirements for single family, rural, and multiple residences; stores,

hotels, motels, laundries, and other commercial establishments; schools, public buildings, and fire protection. Industrial uses of water are primarily represented by fruit, nut, and vegetable processing, and petroleum production and refining. Data presented in State Water Resources Board Bulletin No. 12[11] indicate that the present utilization of water for urban uses in Ventura County exceeds 20,000 acre-feet per year. Under ultimate conditions, it is estimated that use of water for urban purposes will increase more than ten-fold and probably exceed 300,000 acre-feet per year.

Recreational Use

Fishing, swimming, boating, and aesthetic enjoyment are the principal recreational uses of surface waters in Ventura County. Areas of fishing include the Pacific Ocean, Matilija and Piru Lakes and the upper reaches of such streams as Sespe and Piru Creeks. Beaches are utilized for swimming and bathing. Several resort areas and camping grounds in Ventura County have private swimming pools. Boating is confined almost entirely to the Pacific Ocean, Lake Sherwood, and Piru Lake.

Fish and Wildlife

The surface waters of Ventura County are extensively utilized for the preservation and propagation of fish and wildlife. Surface waters of major and minor streams are necessary to maintain animal and bird life. The California State Department of Fish and Game maintains a fish hatchery at Fillmore which obtains its water supply by pumping from Piru Basin. Many of the creeks and lakes in Ventura are regularly stocked with trout. These include eight of the larger streams and Piru, Matilija and Rose Valley

Lakes. In the Pacific Ocean both surf and deep-sea fishing are important recreational and commercial activities.

Waste Disposal

In a semiarid area, such as Ventura County, multiple use generally must be made of available water resources. Conflicts will often develop where pressure for minimizing the cost of treating sewage and industrial waste is opposed to the preservation of water quality for beneficial uses, such as for domestic and industrial water supply, irrigation, maintenance and enhancement of fish and wildlife, and recreation. Proper administration and utilization of available water resources for waste disposal involves reconciliation, so far as possible, of these essential, but inherently competitive uses of water.

All of these uses must be considered legitimate and their relative importance to the economy of the state and county must be evaluated. Whenever a conflict arises, considered analysis of the situation will be required in order to establish priorities of use and set waste discharge requirements. The best interests of the State will be served through efforts to achieve a balanced agricultural, urban, and industrial economy. This necessarily implies the balanced use of available water resources for the many purposes demanded.

The control of pollution of water supplies must be fully integrated and coordinated with the other aspects of water development and use. The keynote to a successful and efficient pollution

control program is prevention. Experience in control activities has shown that prevention is better and cheaper than abatement. The administration of waste disposal activities should provide for the maintenance of the highest practicable level of water quality. There must be no possibility of deterioration of water quality to a degree which precludes use of the available waters for necessary purposes, present or potential. The various types of wastes disposed to the waters of Ventura County, together with their effects upon such waters, are discussed in greater detail in Chapter VI, "Water Quality Problems".

CHAPTER IV. WATER QUALITY CRITERIA

Ventura County is primarily an agricultural area, with citrus and truck crops constituting the major segment of the economy. These crops, particularly citrus, require good quality water supplies to sustain vigorous growth and maintain high production. Water of this quality is available, as evidenced by the high crop yields obtained. However, mineral analyses indicate that poor quality waters may be found in certain of the rivers and creeks during periods of low flow. Ground waters derived from certain of the geologic formations also are of inferior quality. Further, recent depression of piezometric levels in the coastal plain to below sea level has permitted sea-water intrusion into the Oxnard Plain Basin.

Dissolved Constituents in Ground and Surface Waters

Precipitation, as it reaches the earth, normally contains few dissolved solids, although it may contain carbon dioxide and oxygen. These waters, in their passage to the sea, either on the surface or through the ground, dissolve minerals from the materials and rocks with which they come in contact. The amount and type of minerals dissolved reflect the composition of the material with which the water comes in contact and the hydrologic conditions governing the rate of movement of the water. In addition, salts, and other pollutants may be added to water by industrial waste, sewage,and irrigation return wastes. The significance as regards source and effect on usefulness of water, of each of the principal constituents normally found in water is discussed in the following paragraphs.

Calcium (Ca)

Calcium is dissolved from practically all rocks, the highest concentrations usually being found in waters which have been in contact with limestone, dolomite, and gypsum. Irrigation waters containing a large percentage of this constituent, with respect to other bases, are desirable, as a calcium saturated soil is permeable and easily worked.

The presence of calcium in domestic and industrial water supplies, however, results in a hard water. Calcium is largely responsible for the formation of scale in boilers and water pipes. Its reaction with stearates in soap products prevents lathering and produces a gray scum commonly called "bath tub ring".

Magnesium (Mg)

Magnesium is dissolved primarily from volcanic and dolomitic rocks, although large amounts may also originate from the leachings of weathered soils and from marine deposits. Magnesium reacts with soil in much the same manner as calcium and its effects in regard to hardness are similar to those of calcium. For domestic use, the upper limit of concentration is usually maintained somewhat less than 200 parts per million as concentrations above this level may cause taste problems. High magnesium concentrations, when associated with high sulfate content, may cause drinking water to have a laxative effect.

Sodium (Na) and Potassium (K)

Sodium and potassium are dissolved from practically all rocks.

Fresh water supplies having very low concentrations of dissolved solids usually contain as much potassium as sodium. However, as these and other constituents increase in concentration, the relative proportion of sodium generally becomes much larger. Moderate quantities of sodium and potassium have little effect on the usefulness of water. For industrial purposes, waters containing more than 50 to 100 parts per million of a combination of these two elements may require careful operation of steam boilers to prevent foaming. Its presence in water, in combination with carbonate, promotes corrosion in boiler tubes, condensate lines, and hot water systems.

For irrigation use, waters having a high per cent sodium, $\frac{Na \times 100}{(Na+K+Ca+Mg)}$ (constituents expressed in epm), will, as a result of cation exchange, cause dispersion of the soil, reducing its permeability and tilth.

Carbonate (CO_3) and Bicarbonate (HCO_3)

These two constituents are derived principally from dolomite, limestone and other rock minerals. They are closely related and comparative concentrations may change with variations in the pH. In California the bicarbonate constituent is normally the predominant acid radical in both surface and ground waters.

Sulfate (SO_4)

Sulfate is dissolved from many types of rocks and soils. It is derived in large quantities from gypsiferous deposits and from shale deposits of marine origin. Its presence is particularly significant in waters that contain large amounts of calcium and magnesium, as its combination with these two constituents may cause deposits of hard scale in water pipes, hot water heaters, and boilers. For irrigation use, when sulfate is combined with magnesium and sodium, in the absence of sufficient calcium to precipitate sulfate from the soil solution, it may reach concentrations sufficient to become injurious to plants.

For domestic use, when concentrations in excess of 500 parts per million of sulfate are combined with magnesium and/or sodium, there is a noticeable laxative effect. This condition reflects the probable unsuitability of high sulfate waters for domestic use.

Chloride (Cl)

Chloride, present in nearly all waters, is dissolved originally from rocks and natural salt deposits. Sewage and some industrial wastes are also rather heavily charged with this constituent. Large amounts of chloride in water render it unsatisfactory for drinking purposes and for use in processing food beverages. Chloride may be especially harmful in water intended for irrigation use as it may cause subnormal growing rates and burning of leaves.

Nitrate (NO_3)

Nitrate, when occurring in ground water in quantities exceeding a few parts per million, is usually dissolved from evaporates, such as dry salt

beds, or originates from soil percolate charged with fertilizer losses and the by-products of organic decomposition. In rare instances nitrate may be derived from magmatic sources.

Nitrate is of particular significance from the standpoint of public health. Methemoglobinemia (cyanosis) among infants, in many cases, appears to have been due to concentrations of nitrate generally exceeding 10 parts per million as nitrogen (44 ppm as NO_3) in the household water supplies. For industrial uses it has been reported that about 2 parts per million of nitrate in boiler feed water tends to decrease intercrystalline cracking in boiler steel.

Boron (B)

In nature, boron is never found in the uncombined or elemental state. It occurs in the form of boric acid or, more commonly, as borate, especially in regions that are or have been volcanic. It is not a rare element and is widely distributed. The known boron deposits in the United States are located principally in the semiarid regions of the west[12].

Boron, as an ingredient in washing compounds and cleansers, is widely used both in the home and industry. Its concentration in water is important to agriculture for two reasons; first, it is essential in very small amounts to the growth of many, but not all, plants and, second, it is extremely toxic to a large number of plants if present in soil solutions in concentrations exceeding a few parts per million.

Total Hardness

Hardness is caused principally by compounds of calcium and

magnesium, although other substances such as iron manganese, aluminum, barium, silica, strontium, and free hydrogen contribute to the total effect. Hardness in water is primarily an economic problem. Its presence requires an increased use of soap, which it coagulates to form an insoluble precipitate, and it forms scale which tends to reduce the efficiency of boilers and plumbing systems. It is usually considered that soft water (100 parts per million or less as $CaCO_3$) will not interfere with the use of water for most purposes, although lower concentrations may be required for use in high pressure steam boilers and for some industrial processes. Water considered moderately hard (101 to 200 parts per million as $CaCO_3$) may in the upper ranges require softening for laundry and industrial use. Very hard waters (exceeding 200 parts per million as $CaCO_3$) usually require some softening prior to use for most domestic or industrial purposes.

Hydrogen Ion Concentration (pH)

The acidic or alkaline nature of water is given in terms of pH, a measure of the hydrogen ion concentration. pH, which denotes the "hydrogen ion exponent" is the logarithm to the base of 10 of (H), the negative sign being omitted. A neutral solution has a pH of 7.0. As pH decreases the acidity increases and pH increases as the liquid becomes more alkaline. The pH of most water is between 6 and 9.

The hydrogen ion is a potential pollutant because of its corrosive action. In addition, it is related in various ways to other pollutants. It increases the toxicity of such weakly acidic substances as cyanide and it dissolves other pollutants from substances with which it comes in contact. In nature its effect is limited by the presence of buffering substances,

principally bicarbonates. These have a partially neutralizing effect on added acid so that the hydrogen ion concentration is less than it would have been in the absence of the buffer. Similarly, a buffer will increase the hydrogen ion concentration of an added base.

Fluoride (F)

Fluoride is obtained chiefly from fluorspar and cryolite rocks. It is reported that this constituent may be found in the above-named rocks in concentrations similar to that of chloride; however, owing to their origin in only certain types of rocks, high concentrations of fluoride are not common to surface waters but may occur in detrimental concentrations in ground waters.

Fluoride is reported to be toxic to humans in concentrations as low as 180 parts per million (8). However, there is considerable information to indicate that waters containing this constituent in excess of 2 to 3 parts per million may cause mottling on teeth of growing children, particularly, between the ages of 8 and 12. Many dental authorities maintain fluoride concentrations ranging from 0.8 to 1.5 parts per million in drinking water is of considerable aid in the prevention of dental caries. Fluoridation of water supplies to bring the fluoride content within this range is increasingly practiced.

Salts of Heavy Metals

Included in this group are salts of lead, arsenic, hexavalent chromium, selenium, copper, zinc, iron, and manganese. All of these metals in small concentrations may be detrimental to human health, livestock, or

otherwise be objectionable in the water supply.

Certain of these salts, such as lead and arsenic, apparently are toxic to humans in concentrations as low as 0.1 to 0.2 parts per million. Other of the constituents such as copper and zinc will impart an astringent taste to water in concentrations of very few parts per million. Iron and manganese have staining properties at low concentrations and for this reason they are objectionable in waters to be used for domestic and laundry purposes.

Total Dissolved Solids (TDS)

The concentration of total dissolved solids furnishes an indication of the overall mineral quality of a water and as such serves as a valuable criterion for determining the suitability of a water for beneficial use. In general, the total dissolved solids concentration is determined by evaporation. In certain of the analyses presented in Appendixes A and B, the total dissolved solids is reported as the arithmetic sum of the parts per million of all the constituents with the exception of bicarbonate, which is included as equivalent carbonate.

Criteria established for dissolved solids for irrigation use are generally given in the form of electrical conductance or conductivity (EC x 10^6 at 25° C). Conductivity is a physical property of water which depends, to a great extent, upon the quantity of salts in solution. For most waters if the conductance is multiplied by 0.7, a value approximating that of the total dissolved solids is obtained. Further, dividing the conductivity by 100 will give an approximate value of the total anions or cations in equivalent parts per million (epm).

Physical Properties of Water

In addition to dissolved mineral constituents, there are certain physical properties of water which must be considered in determining its suitability for beneficial uses. Included among these are dissolved oxygen, color, turbidity, odor, and taste.

Dissolved Oxygen (DO)

The presence or absence of dissolved oxygen in water is of special significance when dealing with surface waters as it is important to natural purification processes. Natural surface waters of a satisfactory quality should be saturated, or nearly so, with dissolved oxygen (7 to 14 parts per million depending upon the temperature). A consistant deficiency in this constituent is an indicator of organic pollution. In the absence of sufficient quantities of dissolved oxygen, anaerobic bacteria attack organic pollution in the stream and result in the evolution of foul-smelling gases.

Color

In water analyses, the term color refers to the appearance of a water that is free from suspended solids. Color may be due to mineral or organic matter in solution, in suspension, or as a colloid. Its presence is undesirable for domestic and industrial purposes as it may stain laundry, food, or other materials with which it comes in contact. Color may be objectionable in waters used for recreational purposes.

Turbidity

Turbidity is a measure of the suspended and colloidal matter in water. It is generally composed of fine particles of sand and/or clay which are not particularly detrimental to the potability of the water or to most uses. Turbidity in surface water may be removed by chemical coagulation, sedimentation, or filtration. Its particular significance is generally in connection with the spreading of surface waters containing quantities of suspended and colloidal material which tend to clog spreading basins, and thus, reduce infiltration rates. Turbidity is objectionable in waters utilized primarily for recreational purposes.

Odor and Taste

Odors and tastes in water may result from any one or a combination of micro-organisms, living or dead; dissolved gases such as hydrogen sulfide, marsh gas, carbon dioxide or oxygen combined with organic matter; mineral substances such as chloride, iron, carbonates, and sulfates; and phenols or other tarry or oily wastes, especially after chlorination. Some tastes such as those imparted by oxygen and carbon dioxide are pleasant. Most of the other substances mentioned have a disagreeable taste. The odor of a water is dependent to some extent upon its temperature, and the heated odor may be different from the cold odor. While standard methods of analysis of the United States Public Health Service[19] include a quantitative method for the determination of odor, the application of the method depends to a great extent upon the skill and the experience of the analyst. There is no known method for analyzing for taste.

Water Quality Requirements

As stated in Chapter III, the waters of Ventura County are used principally for domestic, municipal, and irrigation purposes with lesser amounts utilized for industrial and recreational purposes. Suitability of these waters for each of these uses depends in part upon the amount and kind of minerals dissolved therein. Water quality criteria for the above beneficial uses are discussed in the following paragraphs, in order that the reader may better interpret the analyses and evaluate the suitability of a particular water for a specific purpose.

Domestic and Municipal Use

Water that is to be used for drinking and culinary purposes should be clean, colorless, odorless, pleasant to the taste, free from toxic salts, and should not contain an excessive amount of dissolved mineral solids. Probably the most widely used criteria in determining the suitability of a water for this use are the "United States Public Health Service Drinking Water Standards, 1946". Limits for mineral constituents in water are divided into mandatory requirements and recommended criteria. The mandatory limits are as follows:

Lead (Pb)	0.1 ppm
Fluoride (F)	1.5 ppm
Arsenic (As)	0.05 ppm
Selenium (Se)	0.05 ppm
Hexavalent chromium	0.05 ppm

Nonmandatory, but recommended, limits are as follows:

Copper (Cu)	3.0	ppm	
Iron (Fe) and Manganese (Mn) together	0.3	ppm	
Magnesium (Mg)	125	ppm	
Zinc (Zn)	15	ppm	
Chloride (Cl)	250	ppm	
Sulfate (SO_4)	250	ppm	
Phenolic compounds in terms of phenol	0.001	ppm	
Total solids	500	ppm	(1000 permitted)

The California State Board of Public Health has defined the maximum safe amounts of fluoride ion in drinking water in relation to mean annual temperature.

Mean Annual Temperature	Mean Monthly Fluoride ion concentration
50° F	1.5 ppm
60° F	1.0 ppm
70° F - above	0.7 ppm

Irrigation

Criteria for the determination of the suitability of waters for irrigation use are usually based upon four factors. These are electrical conductivity ($EC \times 10^6$ at 25° C), chloride concentration, boron concentration, and percentage sodium. Dr. L. D. Doneen of the University of California has proposed criteria based on these four factors as follows:

> "Because of diverse climatological conditions, crops, and soils in California it has not been practical to establish rigid limits for all conditions. Instead, field experience has indicated the classification should be used for the purpose of orientation and as a guide and that local conditions must be considered in judging the suitability of water for irrigation.
>
> "Class 1--Excellent to Good. Regarded as safe and suitable for most plants under any condition of soil or climate.
>
> "Class 2--Good to Injurious. Regarded as possibly harmful for certain crops under certain conditions of soil or climate, particularly in the higher ranges of this class.
>
> "Class 3--Injurious to Unsatisfactory. Regarded as probably harmful to most crops and unsatisfactory for all but the most tolerant.
>
> "Tentative standards for irrigation waters have taken into account four factors or constituents as listed below:

Factor	Class 1 Excellent To Good	Class 2 Good to Injurious	Class 3 Injurious to Unsatisfactory
Conductance ($EC \times 10^6$ at $25^\circ C$)	Less than 1,000	1,000-3,000	More than 3,000
Chloride, epm	Less than 5	5-10	More than 10
Per cent sodium	Less than 60	60-75	More than 75
Boron, ppm	Less than 0.5	0.5-2.0	More than 2.0

(End of quotation)

Actual practice in Ventura County indicates that waters rated as Class 2 or Class 3, particularly in regard to conductance, are successfully utilized to irrigate citrus, a relatively sensitive plant. Accordingly, a method of evaluating the effective salinity of irrigation water, together with standards based on the evaluation, is presented in Appendix F. The tentative classification of irrigation waters in Ventura County established as a result of field surveys in Ventura County is as follows:

Soil Conditions	Effective salinity in milliequivalents: Class 1	Class 2	Class 3
Little or no leaching of the soil may be expected	Less than 3	3-5	More than 5
Some leaching but restricted Deep percolation or slow drainage	Less than 5	5-10	More than 10
Open soils. Deep percolation of water easily accomplished	Less than 7	7-15	More than 15

It should be emphasized that the criteria based upon effective salinity are a substitute for the previously discussed criteria based upon the electrical conductance of water supplies.

Review of the United States Department of Agriculture Soil Survey

of Ventura County[20] indicates that more than 75 per cent of the irrigable lands in this county may be classified as open soils. For this reason water quality criteria for open soils will obtain throughout this report unless otherwise stated.

Industrial Use

Allowable concentrations of dissolved minerals in water to be utilized by laundries, textile manufacturing plants, and various other industries are presented in Table 4, entitled "Water Quality Tolerances for Various Industrial Uses". The values presented in this table are suggested in the Progress Report of the Committee on Quality Tolerances of Water for Industrial Uses, Journal New England Water Works Association, Volume 54, 1940. These limits are tentative and serve only as a guide in evaluating the suitability of water for certain industrial uses. The concentrations listed are those beyond which treatment of the water is generally necessary. Specifications suggested by the above-named committee for boiler waters are more exacting and a separate list of allowable concentrations for that use is presented in Table 5 entitled "Suggested Water Quality Tolerances for Boiler Feed Water".

TABLE 4

WATER QUALITY TOLERANCE FOR INDUSTRIAL USES[a]

Allowable limits in parts per million

Use	Turbidity	Color	Hardness as $CaCO_3$	Iron as Fe[c]	Manganese as Mn[c]	Total solids	Alkalinity as $CaCO_3$	Odor taste	Hydrogen sulfide	Miscellaneous Requirements: Health	Miscellaneous Requirements: Other
Air Conditioning				0.5	0.5			Low	1		No corrosiveness, slime formation.
Baking	10	10		0.2	0.2			Low	0.2	Potable[b]	
Brewing											
Light beer	10			0.1	0.1	500	75	Low	0.2	Potable[b]	NaCl less than 275 ppm (pH 6.5-7.0).
Dark beer	10			0.1	0.1	1,000	150	Low	0.2	Potable[b]	NaCl less than 275 ppm (pH 7.0 or more).
Canning

(b) Limits applicable only to feed water entering boiler, not to original water supply.

(c) Except when odor in live steam would be objectionable.

(d) Depends on design of boiler.

CHAPTER V. WATER QUALITY

This chapter discusses the quality of the ground and surface waters in Ventura County. It also includes a discussion of the prospective quality of imported supplemental supplies which may be made available to Ventura County in the future. Based upon complete and partial mineral analyses, the character and quality of surface waters and the variation of quality with changes in flow is derived. The character and quality of ground waters, including changes which have occurred in the interval between this investigation and the investigation reported in Bulletin No. 46[1], is also discussed.

Sources and Character of Data

Basic data used to evaluate the quality of water in Ventura County include complete and partial mineral analyses of samples collected from wells and streams during the period 1951 to 1958 in the Department of Water Resources' monitoring programs, historical data from Bulletin No. 46A of the Division of Water Resources, and data from files of Fruit Growers Laboratory and of the Ventura County Farm Advisor. Analyses of samples collected from wells in the vicinity of Port Hueneme in 1954, and related data obtained by the Division of Water Resources in a study conducted for Los Angeles Regional Water Pollution Control Board (No.4) have also been utilized. A total of 2,750 complete and 2,279 partial analyses, exclusive of those published in Bulletin No. 46A[2] have been used in studies made for this report. The complete and partial analyses of surface waters are presented in Appendixes A and G, analyses of ground water are presented in Appendixes B and H, analyses of heavy metals and trace constituents determined for about 346 samples are presented

in Appendix B, Tables B-17 and H-17 and partial analyses of selected wells of long record are presented in Appendix C. Analyses presented in Bulletin No. 46A have not been reproduced in this report.

Complete mineral analyses reported in this bulletin include the determination of calcium, magnesium, sodium and potassium, carbonate, bicarbonate, chloride, sulfate, nitrate, fluoride, boron, total dissolved solids, electrical conductance (EC x 10^6 at 25° C), pH, per cent sodium, and effective salinity. Partial mineral analyses include determination of chloride, bicarbonate, pH, and electrical conductance. In some instances, the boron determination was included in the partial mineral analysis. Analysis for trace constituents included the determination of iron, aluminum, manganese, chromium, zinc, copper, lead, silica, and arsenic. In some instances determinations were also made for strontium, barium, nickel, silver, tin, molybdenum, and vanadium.

Concentrations of the principal constituents in a complete mineral analysis are reported in Appendixes A and B in both parts per million (ppm), a weight basis, and equivalents per million (epm), a chemical equivalent basis. Exceptions are boron, fluoride, and total dissolved solids, which are reported in ppm only. To convert equivalents per million to parts per million the concentration in equivalents per million should be multiplied by the equivalent weight of the ion. To convert parts per million to equivalents per million the concentration in parts per million should be divided by the equivalent weight of the ion. Equivalent weights of the principal constituents found in water supplies are presented in the following tabulation:

Cation	Equivalent weight	Anion	Equivalent weight
Calcium	20.0	Carbonate	30.0
Magnesium	12.2	Bicarbonate	61.0
Sodium	23.0	Chloride	35.5
Potassium	39.1	Sulfate	48.0
		Nitrate	62.0

In the following discussion the terms used to describe the chemical character of water are specific. For example, a sodium type water is a water in which the sodium is equal to or greater than 50 per cent of the cations (usually includes sodium, potassium, calcium, and magnesium). A sodium-calcium water is a water in which sodium is more abundant than calcium but is less than 50 per cent of the total cations. A chloride water is a water in which the chloride is equal to or greater than 50 per cent of the anions (usually includes carbonates, bicarbonate, chloride, and sulfate).

The chemical character of a water may be depicted graphically using a geochemical chart[15] such as that shown on Plate 11. By utilization of this chart, it is possible to compare the character of two or more waters. If two waters of different character are mixed it is logical to presume that the character of the resulting mixture will be a combination of the characters of the two waters. Utilizing this principle it is possible, using a geochemical chart, to determine graphically which of various sources of supply are affecting a water body and, more specifically, which of several sources of degradation are causing deterioration.

Quality of Surface Water

The quality and character of surface waters in Ventura County are extremely variable, both areally and with quantity of flow. In general,

the quality of the surface water fluctuates inversely with flow as illustrated on Plate 9,entitled "Relationship Between Discharge and Total Dissolved Solids Concentration in Santa Clara River", and Plate 10, entitled "Relationship Between Discharge and Total Dissolved Solids Concentration in Tributaries of Santa Clara River". This is because low flows are generally derived from effluent ground water, which has a greater opportunity to dissolve salts than has rapid runoff from rainfall.

Analyses may also indicate fluctuations in quality at similar flows. For example, samples collected during the early part of the rainy season generally contain greater salt concentration than samples collected at an identical flow in the latter part of the season, and a sample collected during the rising stage of a flood may contain greater salt concentrations than a sample collected at the same flow during the falling stage. Thus, the quality of surface water varies with discharge and time with respect to both season and flood crest.

In the following paragraphs the character and quality of the surface waters are described for each of the stream systems in Ventura County, Ventura and Santa Clara Rivers, and Calleguas and Malibu Creeks. The locations of surface sampling points are delineated on Plates 7A, B, and C, entitled "Location of Surface and Drainage Water Sampling Stations" An explanation of the numbering system used is given in Appendix A.

Ventura River System.

Water of good quality for domestic, municipal, industrial, and irrigation uses is found in the Ventura River above Foster Park, during periods of high flow, generally reflecting the quality of the principal tributaries above this point, namely, Coyote, San Antonio, and Matilija Creeks. However,

during periods of low flow, these waters may contain concentrations of certain constituents which render them marginal for irrigation use. This is indicated by the data presented in Table 6, entitled "Summary of Character and Quality of Surface Flow in Ventura River System".

TABLE 6

SUMMARY OF CHARACTER AND QUALITY OF SURFACE FLOW IN VENTURA RIVER SYSTEM

Stream	Station number	Average composition of waters in per cent of epm values (high flow / low flow)						Range in boron ppm (high flow / low flow)	Range of total dissolved solids ppm (high flow / low flow)	Range of effective salinity epm (high flow / low flow)	Quality classification for irrigation use (high flow / low flow)
		Ca	Mg	Na	HCO_3	SO_4	Cl				
Ventura River	42-0.5	32 / 29	34 / 20	34 / 51	33 / 21	49 / 38	18 / 41	0.3-0.6 / 0.7-1.9	760-853 / 1335-1619	8.2 / 14.5-19.6	2 / 2-3
Canada Larga	42-4.5-0.2	44 / 22	26 / 29	30 / 49	18 / 14	71 / 70	11 / 16	0.4 / 1.1-1.2	1444 / 2775-3298	12.0 / 31.9-37.6	2 / 3
Ventura River	42-5.7	54 / 54	28 / 22	18 / 24	41 / 40	49 / 39	10 / 21	0-0.4 / 0.4-0.5	259-611 / 668-1037	1.3-7.4 / 4.8-8.6	1-2 / 1-2
Coyote Creek	42-6.0-0.3	56 / 50	26 / 27	18 / 23	50 / 45	38 / 41	12 / 14	0.1-0.2 / 0-0.27	272-614 / 342-840	1.9-4.4 / 3.2-8.6	1 / 1-2
San Antonio Creek	42-7.7-0.2	57 / 54	27 / 24	16 / 22	40 / 31	48 / 49	12 / 20	0.2 / 0.2-0.5	226-458 / 998-1209	1.2-3.8 / 7.8-8.4	1 / 2
Matilija Creek	42-15.6-0.2	55 / 48	32 / 22	13 / 30	39 / 31	56 / 45	5 / 24	0.1-0.30 / 2.1-2.6	424-545 / 789-929	2.3-4.5 / 6.5-7.9	1 / 3

The character of the waters flowing in the Ventura River above Foster Park generally reflects the character of the three principal tributaries, as may be observed from the data presented in Table 6. However, the data are insufficient to correlate in detail the effect of any one of the tributaries on the parent stream. The predominant cation is calcium at both high and low flows in nearly all cases, while the anion character is principally sulfate-bicarbonate. Because of the predominantly calcium character of the flow in this river, and high concentrations of dissolved salts, the waters are generally very hard.

Mineral analyses of samples collected during periods of low flow in Matilija Creek, at a point below the dam, show boron concentrations exceeding 2.0 ppm prior to December, 1951, when the reservoir filled and spilled for the first time. After that date, boron concentrations in samples collected below the dam have varied from 0.1 to 1.0 ppm. Source of this boron is believed to be water from two springs seeping from Cretaceous deposits located in an upstream portion of the watershed.

Data were presented in Bulletin No. 46[1] to show that Wheeler Springs affect the boron concentration in the flow in the North Fork of Matilija Creek. Although data collected during this investigation at station 42-15.6a-0.7 does not seem to confirm this effect, the samples were collected during periods of relatively high flow and it is probable that the effect of flow from Wheeler Springs is masked by runoff from rainfall on the watershed tributary to the station.

Data presented in Table 6 suggest the flow in Canada Larga at station 42-4.5-0.2 to be Class 2 for irrigation use during periods of high flow and Class 3 during periods of low flow because of the excessive

dissolved solids and high effective salinity. By inspection of Table A1 of Appendix A it may be seen that tributaries to Canada Larga, namely, Cash, Sulphur Canyon, and Lion Canyon Creeks, also discharge poor quality waters which are calcium-sodium sulfate in character. Origin of these poor quality waters is probably geologic, since the surface watershed tributary to these streams consists primarily of Pico and Santa Barbara formations. It is known that gypsum crystals (Calcium sulfate) are commonly found in these deposits.

The effect of streams such as Canada Larga which are tributary to the Ventura River below Foster Park is evidenced by the data presented in Table 6 for the Ventura River at station 42-0.7. These data indicate that even the higher flows at this station exhibit effective salinities of sufficient magnitude to classify the waters as marginal for irrigation use. An additional effect of discharges to the Ventura River by tributaries below Foster Park is an increase in the percentage of sulfate between stations 42-5.9 and 42-0.7.

Rincon Creek and those small streams discharging to the Pacific Ocean between Rincon Creek and the Ventura River have been included in the Ventura River system. There is a paucity of data with which to evaluate the quality of the surface flow in these streams. However, available analyses presented in Table A1 of Appendix A suggest that waters of Rincon Creek are of good quality at flows exceeding one second-foot. At flows below this value, however, the quality appears to depreciate rapidly. Waters in Los Sauces Creek are of very poor quality, at least during periods of low flow.

Hall Canyon Creek, also included within the Ventura River system, discharges to the Pacific Ocean between the Ventura and Santa Clara Rivers. The analyses of the waters of this creek, presented in Appendix A, reveal

them to be of poor quality, with excessive chloride and boron concentrations. As described in Chapter VI, this creek has a history of pollution by oil brine discharges, which generally contain high concentrations of these constituents. It is considered that the available analyses reflect, to some degree at least, the effect of the brine discharges and not the native quality of Hall Canyon Creek.

Santa Clara River System

During periods of relatively high flow, the waters of the Santa Clara River and its tributaries are of good quality and suitable for domestic, municipal, industrial, and irrigation uses. However, during periods of low flow, certain of the streams exhibit characteristics which reduce the quality for irrigation purposes to Class 2 or Class 3 and impair suitability for prevailing uses. In general, the character of both high and low flow waters is calcium to calcium-sodium sulfate and the parent stream generally reflects the character and quality of its tributaries. However, data are insufficient to correlate, in any detail, the effect of any one tributary on the Santa Clara River. Because of the predominantly calcium character, many of the surface waters are very hard. All available analyses of surface waters flowing in the Santa Clara River and its tributaries are presented in Appendix A, Tables A2 and G2. Data for certain stations is given in Table 7, entitled "Summary of Character and Quality of Surface Flow in Santa Clara River System". Locations of sampling points are shown on Plate 7B.

TABLE 7

SUMMARY OF CHARACTER AND QUALITY OF SURFACE FLOW IN SANTA CLARA RIVER SYSTEM

Stream	Station number	Average composition of waters in per cent of epm value (high flow / low flow)						Range in boron ppm (high flow / low flow)	Range of total dissolved solids ppm (high flow / low flow)	Range of effective salinity epm (high flow / low flow)	Quality classification for irrigation use (high flow / low flow)
		Ca	Mg	Na	HCO_3	SO_4	Cl				
Santa Clara River	43-4.5	45 / 34	27 / 23	28 / 43	30 / 15	61 / 76	9 / 9	0-0.6 / 0.6-0.9	440-1022 / 1342-2018	3.1-9.0 / 13.3-22.3	1-2 / 2-3

Santa Clara River	43-17.0	44 / 44	25 / 29	31 / 27	23 / 25	64 / 65	13 / 10	0.7-1.4 / 0.6-0.8	962-1731 / 1212-1675	8.5-14.7 / 9.5-14.5	2 / 2
Sespe Creek	43-21.5-6.0	56 / 40	25 / 18	19 / 42	43 / 30	51 / 40	6 / 30	0.1-0.7 / 1.1-4.1	149-526 / 497-848	0.9-3.9 / 4.8-8.3	1-2 / 2-3
Hopper Creek	43-28.9-1.0	51 / 29	24 / 32	25 / 39	37 / 29	58 / 65	5 / 6	0-0.3 / 0.2-0.6	411-646 / 1373-2120	1.5-6.00 / 13.1-19.7	1 / 2-3
Piru Creek	43-31.8-1.3	49 / 38	28 / 30	23 / 32	31 / 26	64 / 66	5 / 8	0.1-1.5 / 1.5-1.7	291-918 / 838-1442	2.4-8.2 / 8.5-12.0	1-2 / 2
Santa Clara River	43-34.5	46 / 36	27 / 30	27 / 34	22 / 24	70 / 87	8 / 9	0.2-0.6 / 0.4-1.3	516-1816 / 898-3157	4.5-16.6 / 9.0-32.0	1-3 / 2-3

The quality of the surface waters entering the county in the Santa Clara River is represented by analyses of samples collected at station 43-37.5. These waters, which typically contain high percentages of sulfate, range from Class 1 to Class 3 for irrigation use even during periods of high flow. They may contain dissolved solids concentrations ranging as high as 1000 ppm. However, boron concentrations are generally within limits for use on even the most sensitive crops. During periods of low flow the quality of waters at this station ranges from Class 2 to Class 3 for irrigation purposes with effective salinities reaching 30 epm, total dissolved solids sometimes exceeding 3000 ppm, and boron concentrations often greater than 1.0 ppm.

Piru Creek, a major tributary to the Santa Clara River, is generally a calcium-magnesium sulfate water of only moderate salinity, even during periods of low flow. However, with the exception of periods of flood flow, waters of this stream contain boron concentrations of such magnitude as to render them unsuitable for irrigation use on the more sensitive crops. Analyses indicate that flows as large as 200 or more second-feet must be reached before boron concentrations consistently become less than 1 ppm. Source of this boron appears to be, in part, Seymour and Lockwood Creeks which drain Lockwood Valley. Bulletin No. 46[(1)] reports that along the north side of this valley there are boron minerals, chiefly colemanite, which on weathering yield boron salts. Analyses of waters derived from springs in this area indicate boron concentrations as high as 32 ppm. Previous studies further suggest that not all of the boron in Piru Creek is derived from Lockwood Valley, since waters from Agua Blanca Creek and other minor streams in that vicinity contain relatively high concentrations of this constituent.

Sespe Creek, another major tributary of the Santa Clara River,

discharges waters containing a relatively low total dissolved solids concentration even during periods of low flow. However, during periods of low flow, boron concentrations are high. Analyses of samples collected at times when flows were less than about 30 second-feet indicate concentrations of this constituent usually too high to be suitable for use on citrus, walnuts, and other boron sensitive crops. Inflow from Hot Springs Creek appears to be one of the more important boron sources. Of interest concerning the character of waters of Sespe Creek is the higher percentage of chloride found during periods of low flow. While the increased percentage of chloride is accompanied by an increase in chloride concentration the values are not of sufficient magnitude to render the waters unsuitable for beneficial uses. Source of the chloride appears to be, at least in part, the flow from Hot Springs Creek. Four analyses of this creek presented in Bulletin No. 46A[2] show relatively high concentrations of this constituent. Historically, oil brines have been discharged directly to Sespe Creek and to Tar Creek, a tributary. While there is no direct evidence of the effect of these brine discharges it seems probable that they have contributed to the total amount of chloride in the waters of Sespe Creek.

Hopper and Santa Paula Creeks, important tributaries of the Santa Clara River, generally discharge water of good quality during periods of high flow. During periods of low flow, Santa Paula Creek generally maintains good quality, but the waters of Hopper Creek become marginal or unsatisfactory for irrigation or domestic use.

In addition to the creeks discussed above, there are many small streams discharging into the Santa Clara River and its principal tributaries. On the basis of the scattered analyses presented in Table A7 of Appendix A,

these appear to have generally poor quality water during periods of low flow. These minor tributaries include Aliso Canyon, Wheeler Canyon, Adams, North Tapo Canyon, and Salt Creeks, all tributary to the Santa Clara River; Mud Creek, tributary to Santa Paula Creek; Little Sespe Creek, tributary to Sespe Creek; and Modelo Canyon and Holser Canyon Creeks, tributary to Piru Creek.

Data presented in Table 7 for Santa Clara River at station 43-17.0 indicate the waters of the river at this point to be Class 2 for irrigation use during periods of both high and low flow. The highest flow for which analyses are available is 1500 second-feet. The analyses of samples collected at this station during periods of low flow probably represent the quality of rising water effluent of Fillmore Basin and entering Santa Paula Basin.

Analyses of the Santa Clara River at station 43-4.5 generally represent the quality of waters which constitute the principal recharge waters for the Oxnard Forebay Basin, and consequently the Oxnard Plain Basin. Available data indicate these waters are Class 1 for irrigation use during periods of high flow, and range from Class 2 to Class 3 during times of low discharge.

Calleguas Creek System

Many of the streams of the Calleguas Creek system discharge relatively minor amounts of water and flow generally continues only for short periods of time following rainfall. For this reason, there is a paucity of data with which to evaluate the quality of surface waters of this system.

In general, data exhibited in Tables A3 and G3 of Appendixes A and G for Calleguas Creek near the Camarillo State Hospital station 44-6.5,

suggest that the quality of these waters varies from Class 1 to Class 2 for irrigation use, with total dissolved solids concentration ranging from about 380 to 1060 ppm, the lower concentration being associated with the higher discharges. Calleguas Creek at station 44-9.7, above its confluence with Conejo Creek, appears on the basis of seven analyses to be of somewhat better quality, with total dissolved solids concentration generally less than 900 ppm. The data available indicate the character of the waters flowing in this creek to be calcium sulfate.

Analyses of Conejo Creek, a tributary of Calleguas Creek, at station 44-7.9-3.0 indicate these waters to be of excellent quality with total dissolved solids concentrations ranging less than 264 ppm. However, at station 44-7.9-12.8 the low flow quality ranges from Class 2 to Class 3, with higher total dissolved solids and effective salinity values. The cation character of the waters in Conejo Creek varies from calcium-magnesium to magnesium-calcium,while the anion character at station 3.0 is bicarbonate-sulfate and at station 12.8 is sulfate.

Analyses of samples collected from Arroyo Simi on March 7, and 15, 1952, present a rather interesting phenomenon. The sample collected March 7, at a time when discharge was estimated to be 60 second-feet, contained 679 ppm of total dissolved solids while the sample collected March 15 during a flow estimated to be 2000 second-feet,contained 1453 ppm total dissolved solids. The character of both samples was calcium sulfate, the only difference in the two samples being a higher percentage of calcium and sulfate in the March 7 sample. The analysis of a sample collected at this station on April 16, 1952, showing over 7000 ppm total dissolved solids, is considered to be effluent flow from a semiperched zone which exists in the western portion of Simi Basin.

Analyses of samples collected from Tapo Creek, a tributary of Arroyo

Simi, indicates the waters of this creek to be of Class 3 quality for irrigation and generally unsuitable for domestic use during periods of low flow. As in the Arroyo Simi, the quality of the flow on March 7, 1952, was considerably better than the quality on March 15 of the same year although the flow on the latter date was five times that of the former.

Data collected for Revolon Slough at station 44-2.1-1.7 indicate the water to be of poor quality. However, this slough is primarily used as a wasteway for the disposal of irrigation drainage from the Oxnard Plain, and Pleasant Valley ground water basins, and the character of the analyses for this stream presented in Table A3 of Appendix A strongly suggests that irrigation drainage represents the primary source of the sample collected.

Malibu Creek System

Data for this stream system are limited to seven analyses presented in Tables A4 and G4 of Appendixes A and G, three from Big Sycamore Creek and three from Little Sycamore Creek and one from La Jolla Creek. These analyses indicate the waters to be of good quality and suitable for beneficial uses. However, both streams discharge waters that are classified as very hard.

Quality of Ground Water

The quality and character of ground waters in Ventura County vary widely, depending upon the geologic formations from which the water is derived; the quality of the ground water recharge; the extent to which the ground water has been affected by pollutants and degradants; and fluctuations resulting from cyclic periods of above normal and subnormal water supply. The suitability of the ground waters for beneficial use depends

upon the quantity and type of salts in the water. For irrigation use, suitability depends on soil drainage, climate, and sensitivity of the crop.

In general, much of the ground water in Ventura County is of suitable or marginal quality for the prevailing beneficial uses although many of the waters are very hard. For this reason, water softening may be desirable before use of ground water for domestic and certain industrial purposes. There is discernible variation in both the character and quality of ground water, not only between drainage systems but between basins within drainage systems and aquifers within basins.

In view of this diversity, the ensuing discussion of ground water quality has, for simplicity of presentation, been divided into drainage systems and subdivided into ground water basins. A tabulation of complete mineral analyses, including a limited number made for trace constituents, of samples collected subsequent to the publication of Bulletin No. 46A[2] is presented in Appendix B, while partial mineral analyses for selected wells are presented in Appendix C. Appendix H contains analyses made subsequent to 1952.

Ventura River System

Ground water basins within this system include Upper Ojai, Ojai, and Upper and Lower Ventura River Basins.

Upper Ojai Basin. In general the ground waters of Upper Ojai Basin are of good quality and suitable for domestic and irrigation uses. This is shown by the following data summarizing the values of total dissolved solids, boron, and effective salinity of samples collected from 12 wells in this basin during the late fall of 1951 and the summer of 1952.

Chemical Property	Maximum	Minimum	Average	Median
Total dissolved solids, ppm.	1249	438	707	605
Boron, ppm.	1.5	trace	0.4	0.2
Effective salinity, epm.	11.8	2.8	5.5	4.0

Ground waters derived from the western part of the basin are calcium to calcium-sodium bicarbonate in character, while the waters found in the eastern part of the basin are primarily calcium sulfate.

In the extreme easterly portion of the basin, the limited occurrence of sodium chloride waters of unsatisfactory quality is indicated. These waters contain total dissolved solids concentrations ranging from 2000-3000 ppm, effective salinities up to 31 epm, and high boron concentrations. In addition, wells 4N/22W-11P1 and 11R1, located on the south of the basin, yield waters containing high boron concentrations. Sources of degradation probably include connate brines seeping from the Modelo shales located on the south side of the valley, and oil brines which, historically, have been disposed to unlined sumps in the eastern portion of the valley. (3).

In general, analyses made subsequent to 1952 show little change in character or quality. One well, however, No. 4N/22W-9R4 increased in salinity from 1249 ppm total dissolved solids in 1952 to 1766 ppm in 1954 and then declined to a value of 1004 ppm in 1958. Table H-1 in Appendix H shows several other wells in which quality has improved between 1951 and 1958.

Ojai Basin. Mineral analyses indicate nearly all the ground waters derived from this basin to be of good mineral quality and suitable for the prevailing beneficial uses. On the basis of analyses of samples from 19 wells collected in 1952, the total dissolved solids content ranges from about 450 to about 1140 ppm and averages 640 ppm. Effective salinity, while ranging from about 3 to over 11 epm, seldom exceeds 6 epm and averages about 4.8 epm. Boron concentrations are in the order of 0.1 ppm and never exceed 0.4 ppm.

In comparison to the data presented in the foregoing paragraph, analyses of samples collected from nine wells in 1933 show that the average total dissolved solids concentration at that time was about 490 ppm. Thus, it is indicated that in an interval of 19 years, the average concentration of total dissolved solids has increased about 150 ppm in Ojai Basin. This increase suggests that the inflow of salts to the ground water body may exceed the disposal of salts therefrom. Sixty-eight analyses of samples collected during the period 1953 to 1957 from 27 wells show this trend of increasing salinity to be continuing. Although this continuing increase indicates a possible adverse salt balance, consideration must be given to the fact that the period of increase has not occurred over an average water supply period.

Ground waters of Ojai Basin are principally calcium bicarbonate-sulfate in character although several of the wells, scattered throughout the basin, yield waters with bicarbonate concentrations exceeding 50 per cent of the total anions. In addition, several wells, including Nos. 4N/22W-6D5, 4N/22W-9B1, and 4N/23W-12K2, produce waters with sulfate as the principal anion and there is one well, No. 5N/22W-32J3, with a chloride concentration exceeding 50 per cent of the total anions.

With the exception of well 6D3, the quality of the water derived from these wells is somewhat inferior to that of waters found in other parts of the basin, as the total dissolved solids content exceeds 1000 ppm. Information is lacking concerning the depth or the deposits encountered while drilling the three wells yielding poorer quality waters. However, it is possible that a portion of this water is in some manner derived from older deposits underlying or bounding the alluvium.

Upper Ventura River Basin. The quality and character of waters derived from wells in this basin generally reflect the quality and character of the surface waters of the Ventura River, particularly those found during periods of high flow. The effect may be seen by reference to Table 8, entitled "Similarity of Quality and Character of Surface and Ground Water in Upper Ventura River Basin". This close correspondence occurs because the primary source of recharge to this basin is deep percolation of surface flow in the river. Furthermore, the shallow alluvial deposits, from which the major portion of ground water in this basin is derived, permit only limited amounts of carryover storage. Hence, ground water storage and quality rapidly reflect changes in quantity and quality of flow in the river.

TABLE 8

SIMILARITY OF QUALITY AND CHARACTER OF SURFACE AND GROUND WATER IN UPPER VENTURA RIVER BASIN

Source	Constituents in percentage equivalents						Boron	Total dissolved solids	Effective salinity
	Ca	Mg	Na	HCO_3	SO_4	Cl	ppm	ppm	epm
Ventura River at Foster Park (high flow)	54	28	18	41	49	10	0.2	500	4.2
Ventura River at Foster Park (low flow)	54	22	24	40	39	21	0.5	841	6.3
Average of eight wells pumping from alluvium of Upper Ventura River Basin	55	25	20	43	37	10	0.5	618	4.6

In general the quality of ground waters produced from this basin may be considered suitable for domestic, municipal, and irrigation uses. Presented below are data which reflect the extreme and average mineral quality attributes of these ground waters. This summary is based upon analyses of 23 samples collected in August of 1952, and April and May of 1953.

Chemical Property	Maximum	Minimum	Average	Median
Total dissolved solids, ppm	1420	370	732	620
Boron, ppm	0.6	0.0	0.3	0.4
Effective salinity, epm	10.4	1.9	5.3	4.8

Analyses made during the period 1953 to 1958 show only minor changes in quality except for several wells in which the 1958 samples showed improvement in quality.

About 75 per cent of the samples collected in 1952 and 1953 and between 1953 and 1958, indicate that the cation character of the ground waters is predominately calcium, although waters of a sodium-calcium and magnesium-calcium type were derived from a few scattered wells. The anion character of the majority of the waters varies narrowly between sulfate-bicarbonate and bicarbonate-sulfate. There are, however, analyses from two wells drilled into deposits in San Antonio Creek which show a sulfate character and nine analyses from wells deriving waters from deposits in Santa Ana Creek, in the vicinity of Meiner's Oaks and along the east side of the Ventura River above Oakview, which show a bicarbonate character. Comparison of the locations of wells of deviating anion character with the areal geology, suggests that the sulfate waters are derived from shale deposits, while nearly all waters of bicarbonate character are from wells drilled into the Sespe formation or adjacent deposits.

The bicarbonate character of waters, produced from the Sespe formation, is indicated by the analysis of spring 4N/23W-14A1, which emanates from these deposits. The excellent quality of the water from this spring suggests that waters of the Sespe formation are of good quality near the surface. However, data obtained from electric logs of wells drilled into these deposits suggest that saline waters may occur at depth.

There are two wells located adjacent to San Antonio Creek, which yield waters with total dissolved solids and effective salinity values considerably above average. These waters are Class 2 for irrigation use,

have a sulfate anion character, and are probably derived from Tertiary deposits such as the Modelo shale and the Vaqueros formations. However, only a minor quantity of water is derived from these deposits and their effect on the overall quality of the waters in the Upper Ventura River Basin is considered minor.

Lower Ventura River Basin. There are very few water wells drilled into the alluvium of this basin and mineral analyses with which to interpret the quality of the ground water are almost completely lacking. Furthermore, available analyses present somewhat conflicting information. Analyses of well 3N/23W-33N1 suggest the waters to be of very poor mineral quality, while the analysis of well 3N/23W-33C1 suggests excellent mineral quality. Of significance, however, is the fact that these samples were collected by bailing the wells and for an extended period prior to sampling neither of the wells had been pumped. The effect of such a period of idleness is evidenced by the analyses of well 3N/23W-33N1 presented in Appendix B, Table B3, wherein samples of rather different quality were found at variations in depth of only 10 feet. These differences may be the result of slow settling of ions in solution with a consequent increase in salt concentration near the bottom of the well and decrease in concentration near the top.

Discussion presented in Bulletin No. 46[1] indicates that concentrations of chloride, boron, and dissolved solids in the ground waters of the basin make the waters unsuitable for beneficial use. This is substantiated by reports from local farmers and by the electric log of well 2N/23W-5P1, which suggests salty water to occur for the first 300 feet. It is further reported that hydrogen sulfide gas may be found in these waters, particularly during periods when water levels are lowest, and that the waters often contain oil.

Reasons for this poor quality water are obscure, although it is reported that oil field waste disposal practices in the early history of the Ventura Oil Field may have polluted ground water.

The quality of ground waters derived from the alluvial deposits in Canada Larga, a tributary of the Lower Ventura River Basin, is shown by the analyses of well 3N/23W-12D1 presented in Appendix B, Table B3. These waters are apparently Class 3 for irrigation uses and unsuitable for domestic use. The source of the poor quality water is considered to be geologic in origin, since the salts are probably derived from nearby deposits of Tertiary age.

Santa Clara River System

Ground water basins within this drainage system include Piru, Fillmore, Santa Paula, Mound, Oxnard Forebay, Oxnard Plain, and Pleasant Valley. The character and quality of ground waters in each of these basins and the suitability of the waters for prevailing and anticipated beneficial uses are discussed in detail in the following section.

Piru Basin. Ground waters, derived from the alluvium and underlying San Pedro formation within Piru Basin, range in quality from Class 1 to Class 3 for irrigation use. In some instances, certain of the constituents, notably magnesium, fluoride, sulfate and total dissolved solids, exceed the recommended and/or mandatory limits for domestic use established in the United States Public Health Service Drinking Water Standards. Summarized below are pertinent statistics relative to total dissolved solids, boron and effective salinity for a series of samples collected from 26

wells during the last week of May, 1952. These data emphasize the variation in quality in this basin.

Chemical Property	Maximum	Minimum	Average	Median
Total dissolved solids, ppm	3386	778	1320	1477
Boron, ppm	1.3	0.4	0.8	0.8
Effective salinity, epm	25.2	6.9	10.4	11.7

The above data indicate that ground waters in Piru Basin are on the average Class 2 for irrigation use. However, the soils in the alluvium of this basin are in general very permeable and excellent subdrainage is afforded. For this reason, many of the ground waters of this basin have been successfully applied on even the more sensitive of crops. However, the Ventura County Farm Advisor and local farmers have reported that in 1951 citrus and other crops showed symptoms of salt injury of a magnitude sufficient to cause concern. This condition was relieved by heavy rains which fell during the winter of 1951-52, since deep percolation of precipitation considerably reduced the concentration of the soil solution. However, it serves to emphasize the fact that many of the waters of this basin are marginal and that determination of requirements for applied water must consider not only consumptive use requirements, but also an allowance for sufficient irrigation return to prevent excessive concentration of salts in the root zone.

An indication of the changes in quality that have occurred in the ground waters of Piru Basin over a period of time is furnished by analyses of samples collected from 19 wells in 1929. These data show that the average

total dissolved solids content of these ground waters was about 1240 ppm in 1929 compared to an average of 1320 ppm in 1952. Direct comparison of analyses of samples collected from four wells in 1929 and 1952 indicates that during the 23-year period the total dissolved solids content increased from 1125 to 1540 ppm. It is apparent from these data that the ground waters of Piru Basin have experienced an increase in salt content. However, the magnitude of the increase indicated is not necessarily a dependable figure since the period of comparison does not correspond to an average water supply period. Forty-three analyses of ground water from 26 wells for the period 1953-1958 are presented in Table H-4. These analyses indicate that no significant changes in quality or character have occurred during this period.

The character of the ground waters of Piru Basin is consistent, with calcium the most important cation and sulfate the predominant anion. Studies relating quality and location indicate that the water in the upstream portion of the basin contains considerably greater concentrations of dissolved salts than the water derived from the downstream portion. As previously stated, the quality of surface waters of the Santa Clara River at the upstream end of the basin, as evidenced by analyses of samples collected at Blue Cut, station 43-34.5, is very poor. It is considered probable that the higher total dissolved solids concentrations found in the upstream part of the basin reflect the deep percolation of these poor quality surface waters. The lesser quantity of dissolved salts evidenced in the downstream portion of the basin is considered to reflect, at least in part, the influence of waters derived from Piru Creek. The effect of the flows in this creek on ground waters of Piru Basin is emphasized by the high boron concentrations found in the waters derived from wells located in the vicinity of and

downstream of the mouth of the creek where the concentrations of boron are in the order of 1 ppm.

Three of the wells in this basin, Nos. 4N/18W-29P2, 4N/19W-25C1, and 34C2, yield waters of relatively poor quality. The effective salinity of waters from these wells generally exceeds 16 epm and total dissolved solids concentrations are proportionately high. Water levels in well 4N/18W-29P2 are considerably higher than in other nearby wells and the general water table elevation of the basin. The inference is that the water in this well is supplied from older deposits which form the southerly boundary of the alluvial deposits. Concerning the other two wells, similar hydrologic data suggest the effect of ground water emanating from older deposits. However, well 25C1, which is drilled near the mouth of Hopper Creek, may, to some extent, reflect the poor quality waters which are found in this creek during periods of low flow.

There are available analyses of three wells located outside the principal water-bearing formations of Piru Basin, but within the drainage area of the basin. Wells 4N/18W-3Q1 and 3Q2 are drilled into the alluvium of Piru Creek, and well 4N/18W-12P1 into the alluvium of Holser Canyon. The waters derived from the wells adjacent to Piru Creek contain high concentration of boron. The quality of waters derived from the alluvium of Holser Canyon is extremely poor with effective salinity values in excess of 60 epm.

Fillmore Basin. Ground waters of this basin, principally derived from alluvial and San Pedro deposits, vary in quality from Class 1 to Class 3 for irrigation use. Furthermore, certain constituents in waters from various parts of the basin, notably sulfate, fluoride, and total dissolved solids, exceed the recommended and/or mandatory limits for drinking water.

To illustrate the quality traits in this basin, there is presented below a summary of data secured from analyses of samples collected from 44 wells during the months of May and June, 1952.

Chemical Property	Maximum	Minimum	Average	Median
Total dissolved solids, ppm	2661	516	1206	945
Boron, ppm	1.5	0.2	0.6	0.6
Effective salinity, epm	21.2	3.3	9.4	8.3

These data indicate that over 50 per cent of the wells sampled yield waters of Class 2 or Class 3 quality. Because the soils of Fillmore Basin are in general very permeable and there is excellent subdrainage, ground waters of this basin have in the past been utilized without significant crop damage. However, waters which contain concentrations of salts which exceed the average values shown, should be used with care to insure that soil solution concentrations do not increase to the point that injury to crops will result. It is noted that the values presented in the foregoing tabulation indicate a large variation between the average and median figures for total dissolved solids concentration and effective salinity. This variation indicates the effect of a minority of wells yielding water of much poorer quality than the average values.

As an indication of changes which have occurred in the quality of the ground waters of Fillmore Basin over a period of time, comparison of data presented in the foregoing tabulation with data presented in Bulletin No. 46A[(2)] is of significance. Analyses of samples collected from 20 wells

in 1930 indicate that the average total dissolved solids content in the ground waters of Fillmore Basin was about 970 ppm at that time. This is compared to an average total dissolved solids content of about 1200 ppm in 1952. Direct comparison of analyses of samples collected from six wells indicates the average total dissolved solids concentration to have increased from 660 ppm in 1932 to 1090 ppm in 1952. However, the foregoing comparisons do not cover an average water supply period and the magnitude of the increases may not accurately indicate the average rate of increase of salt concentration in this basin. Ninety-three analyses of ground water from 50 wells covering the period of 1953 through 1957 are presented in Table H-5. These analyses indicate that no major changes in ground water quality or character have occurred during this period.

The principal cation in the ground waters of Fillmore Basin is generally calcium, although analyses indicate that there are a few wells producing waters of a calcium-magnesium or calcium-sodium type. Sulfate exceeds 50 per cent of the total anions throughout the major part of the basin, although in ground waters derived from that portion of the basin lying north of Santa Clara River and west of Sespe Creek the predominant anion is generally bicarbonate. These waters are of relatively good quality, although two of the wells, Nos. 4N/20W-25D1 and 26P1, have boron concentrations somewhat in excess of maximum values recommended for use on sensitive crops. No specific water quality data are available with which to determine the source of the water of this character.

A study comparing the quality of the waters on an areal basis revealed that poorer than average quality waters are found in the southern portion of the basin and in a limited area south and west of the City of Fillmore. The waters in the southern portion of the basin have effective salinities generally exceeding 12-15 epm and boron concentrations in the order of 1 ppm, while the waters

found in the vicinity of Fillmore have effective salinity values in the order of 150 per cent of the average for the basin.

Wells in the southern portion of the basin which yield waters of poor quality are found in Sections 8, 9, 10, and 11 of Township 3 North, Range 20 West. The areal extent of degradation is much more widespread in this area than in other areas adjacent to the hills flanking the south side of the Santa Clara River and it is therefore considered that surface runoff from nearby hills is not the sole contributing factor to the poor quality.

Furthermore, it has been previously stated that Tertiary rocks bordering the basin on the south have been eroded by the Santa Clara River, followed by the deposition of up to about 200 feet of Recent alluvium. Most of the wells which yield poor quality water are drilled into this overlying alluvium. Available information does not indicate that any of the wells have been drilled into the Tertiary deposits. It is therefore considered that in this area there is an upward movement of water from the Tertiary deposits which is causing at least part of the indicated degradation.

Ground water movement in this area, as indicated by the contours delineated on Plate 2, is in a westerly direction toward the main stream of the basin. At the present time the extent of appreciable degradation is probably limited by dilution by better quality waters. However, it is believed that during periods when water levels are drawn down in the main part of the basin, an increased volume of this poor quality water moves a greater distance into the basin. It follows that any plan to

operate Fillmore ground water basin as a ground water reservoir should consider the effects of this poor quality water on the overall quality of the water of the basin.

The areal extent of the poorer quality water found south and west of the City of Fillmore is in the form of a triangle with its apex near the point where Sespe Creek discharges into the Santa Clara River and its base through the city. The quality of these waters is Class 2 for irrigation use with effective salinity values in the order of 150 per cent of the average for the basin.

The source of this inferior quality is obscure. However, available data suggest two possibilities: (1) percolate from Pole Creek which, based upon available analyses, discharges waters of relatively poor quality and (2) discharges to cesspools and septic tanks, possibly within the City of Fillmore, which over a long period of time may have caused impairment of ground waters.

Santa Paula Basin. Ground water derived from the Recent and Pleistocene alluvium and the San Pedro formation in this basin varies in quality from Class 1 to Class 3 for irrigation use. In some instances, certain of the constituents, notably sulfate and total dissolved solids, exceed the limits for domestic use recommended by the United States Public Health Service. The following summary illustrates the quality conditions which exist in this basin. The values are computed from analyses of samples from 28 wells collected during the fall of 1951 and the spring of 1952.

Chemical Property	Maximum	Minimum	Average	Median
Total dissolved solids, ppm	2542	800	1349	1198
Boron, ppm	1.9	0.1	0.8	0.6
Effective salinity, epm	21.8	6.1	10.4	9.3

Comparison of the median and average values presented in the foregoing summary suggests that the waters of this basin are generally Class 2 for irrigation use. However, a few wells, yielding water of poor quality, have a discernible influence on the average quality.

Historically, the quality of the waters of Santa Paula Basin has tended to deteriorate with time. Analyses of samples collected from 30 wells in 1931 indicate that the average total dissolved solids content of ground water at that time was about 980 ppm,or about 370 ppm less than the 1951-52 value. Direct comparison of analyses of samples collected from 15 wells indicates that the average total dissolved solids concentration increased from 955 ppm in 1931 to 1220 ppm in 1951. Analyses of water from 34 wells sampled during the period 1953-1958 show no significant changes in quality or character and no notable trends of increase or decrease in salinity throughout the basin.

Santa Paula Basin is the only ground water basin in Ventura County for which historical quality data exists in sufficient quantity to fully justify study and conclusions. Available data comprise analyses of samples collected approximately once each year since 1928. In general, these data indicate that, in the period from 1928 to about 1935 or 1936, the salt concentration in the waters of this basin evidenced a substantial

rise, with increases amounting to as much as 100 per cent of the 1928 concentration. In the period between 1936 and about 1945, salt concentrations decreased, although not to the 1928 level. Between 1945 and 1952, salt concentrations again reached, and in some instances exceeded, 1935 values. An attempt was made to correlate quality fluctuations with hydrologic factors such as rainfall, runoff, and ground water levels. It is indicated that a qualitative relationship does exist, although the data available did not permit the determination of quantitative values.

The cation character of the ground waters of Santa Paula Basin is usually calcium, although several analyses indicate a calcium-sodium character. The principal anion is sulfate, except for water derived from a very few wells located near the mouth of Santa Paula Creek. These latter wells have a sulfate-bicarbonate character similar to that of the high flow waters of the creek.

With respect to geographical location, the ground water derived from the eastern portion of the basin in the vicinity of the mouth of Santa Paula Creek indicates the effect of the high quality waters from this creek on the underlying ground water.

A few wells in this basin produce waters of considerably poorer than average quality. These include wells 3N/21W-16H1, 28M1, and 31C1, and 3N/22W-35P1. In the instance of well 16H1, observations made in the course of water level measurements indicate the well to have a leaky casing, suggesting that the waters are being degraded by a poor quality water, possibly from a localized semiperched body, migrating to the principal aquifer through the leaky casing. A similar occurrence is suspected in the instance of wells 3N/21W-31C1 and 3N/22W-35P1. Both of these wells produce waters of Class 3

quality. They are more than 250 feet deep and yield waters of similar chemical character to the ground water in much of the remainder of the basin, suggesting irrigation return water as the source of deterioration. Suitable methods of construction and abandonment of wells should be developed and utilized in pressure portions of this basin.

Well 3N/21W-28M1, mentioned previously as producing waters of poor quality, is located south of the Oak Ridge fault and adjacent Pico formation. It seems probable that poor quality waters migrating from these older Pico deposits are reflected in the water derived from this well.

In addition to the cited instances of poor quality water, the analyses presented in Appendixes B & H indicate that four wells, Nos. 3N/21W-21B1, 21E1, 21F1, and 21F2, produce waters with boron concentrations exceeding one ppm. These wells which are located downstream from the sewage treatment of the City of Santa Paula have been affected by discharges from the plant.

An additional source of deterioration to the ground waters of this basin is percolation of poor quality surface waters flowing in Wheeler Canyon. Analyses of two wells, Nos. 3N/22W-2G2 and 3N/22W-11H1, suggest the direct effect of waters from Wheeler Canyon on ground waters. Both of these wells produce Class 3 waters with a sodium-calcium sulfate character. The effect of surface flow from Wheeler Canyon is also evidenced in the quality of well 3N/22W-24R1.

Mound Basin. The principal deposits yielding ground water to wells in this basin are of the San Pedro formation, although minor amounts of water are also derived from the overlying Recent alluvial and upper Pleistocene deposits.

The quality of the waters derived from the San Pedro formation, as depicted by analyses of samples collected from 15 wells in June and July of 1952, ranges from Class 1 to Class 3 for irrigation use. The total dissolved solids content ranges from a minimum of 700 ppm to a maximum of 2,599 ppm, with an average of 1,211 ppm and a median of 1,113 ppm; the boron concentration ranges from a minimum of 0.2 to a maximum of 0.6; averaging 0.4; and the effective salinity ranges from a maximum of 20.6 to a minimum of 7.7 epm, averaging 10.1 epm. The median value for effective salinity is 9.6 epm. The character of the waters derived from these deposits is generally calcium-sodium sulfate.

Thirty-five ground water analyses are available from 20 wells covering the period since 1952. With but one exception these analyses show no significant changes in mineral quality or character and do not indicate any basin-wide trends. The exception is analyses from well 2N/23W-5L1 which show a pronounced increase in chloride ion and total dissolved solids content. Insufficient data are available to establish the source of impairment; which may be poor quality waters from adjacent formations, oil well brines, or sea-water intrusion.

Since the soils of this basin are fairly permeable, it is believed that the waters are usable for irrigation. However, as the concentrations increase above the average, care must be taken to prevent an undesirable soil solution condition. Concerning domestic use, certain of the mineral constituents, notably sulfate and total dissolved solids may, in some instances, exceed the limits recommended by the United States Public Health Service.

Information concerning the quality of the waters derived from the alluvium is limited to one analysis from well 2N/22W-10R2. It would appear from these meager data that the water derived from the alluvium is of suitable

quality for established beneficial uses, at least in the vicinity of the cited well.

In Chapter II, it is stated that the San Pedro deposits within the lower portion of the Ventura River drainage area are separated from the overlying Recent alluvium and probably hydrologically interconnected with the Mound Basin. Available water quality data, although meager, tends to support this suggestion. This may be seen from an inspection of Table 9, entitled "Comparison of Quality and Character of Waters in Alluvium and San Pedro Deposits of Lower Ventura River and Mound Basin". This table presents water quality data for high and low flows in the Ventura River, for waters derived from the alluvium of the lower Ventura Basin, for two wells deriving waters from the San Pedro deposits in the Lower Ventura River Basin, and average quality of water from 15 wells producing from the San Pedro deposits in the Mound Basin. This effect is also shown on Plate 11, entitled "Mineral Character of Ground Waters, Mound and Lower Ventura River Basins", graphically illustrating the character of these waters. The data indicate that the water from the two wells producing from the San Pedro deposits in the Ventura Basin is similar in character and quality to the waters in Mound Basin and differs from the waters found in the alluvium of the Ventura Basin and low flows in the Ventura River.

TABLE 9

COMPARISON OF QUALITY AND CHARACTER OF WATERS IN ALLUVIUM AND SAN PEDRO DEPOSITS OF LOWER VENTURA RIVER AND MOUND BASINS

Source	Date Sampled	Average composition of waters in per cent of epm values						Total Dissolved Solids	Boron	Effective Salinity
		Ca	Mg	Na	HCO_3	SO_4	Cl	ppm	ppm	epm
Ventura River Station (42-0.5)										
High flows[a]		32	34	34	33	49	18	760-853	0.3-0.6	8.2
Low flows[b]		29	20	51	21	38	41	1335-1619	0.7-1.9	14.5-19.6
Wells in Ventura Basin alluvium

a From Table 6.

b From Table 6.

c Average of analyses of four thief samples collected at 20, 30, 40, 50 foot depths.

d Average of analyses of samples collected in the summer of 1952 from 15 wells producing from the San Pedro formation.

Oxnard Forebay Basin. Ground water produced from the Oxnard Forebay Basin is derived from Recent and Pleistocene alluvium and the San Pedro formation. The quality of the waters in these deposits, which are contiguous and in hydraulic continuity, is generally Class 2 for irrigation use. Analyses of samples collected from 14 wells in the summer of 1952 indicate a concentration of total dissolved solids ranging from a maximum of 1940 ppm to a minimum of 838 ppm, with an average of about 1270 ppm, and a median concentration of 1245 ppm. The boron content ranges from a minimum of 0.3 ppm to a maximum of 0.9 ppm with average and median values of 0.6 ppm. The effective salinity ranges from a minimum of 7.8 to a maximum of 15.3 epm, with an average of 10.6 and a median of 10.0 epm.

An indication of the quality trend in this ground water basin during a period of 21 years is furnished by comparison of data presented in the foregoing paragraph with analyses of samples collected in 1931. Based upon 7 analyses, the average total dissolved solids concentration was about 1000 ppm in 1931 or about 270 ppm less than the 1952 value. While it appears that there is a general over-all increase in the salt concentration in this basin, the period of record does not correspond to an average water supply period. The magnitude of the difference, therefore, should not be used to determine the average rate of salt concentration increase.

Seventy-two analyses of ground water are available from 27 wells covering the period 1953 to 1958. These analyses indicate only minor increases in dissolved solids and show no significant changes in quality or character.

The character of the ground waters found in the Oxnard Forebay is generally calcium-sodium sulfate, similar to the high flow waters in the

Santa Clara River. Since the area is not only recharged under natural conditions by the Santa Clara River, but also by artificial spreading of this water during periods of high runoff, the similarity to the surface supply is to be expected.

Oxnard Plain Basin. Ground water produced for beneficial use in the basin is derived primarily from the Oxnard aquifer, although some water is obtained from the Fox Canyon aquifer of the San Pedro formation, from discontinuous gravels of the upper San Pedro formation and, in minor amounts, from the Santa Barbara formation and Quaternary alluvium. In addition there is a semiperched ground water body in permeable deposits overlying the clay cap which confines the Oxnard aquifer. These latter waters are of poor quality and there are no known wells which intentionally derive water from this zone.

Nearly all wells for which analyses are presented in Appendix Tables B, B9,and H-9 produce from the Oxnard aquifer. However, there are analyses available for three wells pumping from the Fox Canyon aquifer, one well deriving water from miscellaneous gravels of the upper San Pedro formation, and two wells producing from the Quaternary alluvium. To indicate the quality of the waters from these aquifers, the results of a series of samples collected during the summer of 1952 are summarized in the following tabulation.

Source and chemical property	Maximum	Minimum	Average	Median
Oxnard Aquifer (81 analyses)				
Total dissolved solids, ppm	2071	700	977	914
Boron, ppm	1.1	0.1	0.6	0.6
Effective salinity, epm	17.3	5.7	8.1	7.4

Source and chemical property	Maximum	Minimum	Average	Median
Fox Canyon Aquifer (3 analyses)				
Total dissolved solids, ppm	820	744	770	745
Boron, ppm	0.4	0.1	0.2	0.2
Effective salinity, epm	7.2	6.9	7.1	7.1
Quaternary Alluvium (2 analyses)				
Total dissolved solids, ppm	932	672	802	---
Boron, ppm	0.6	0.4	0.5	---
Effective salinity, epm	7.6	5.4	6.5	---
San Pedro Formation (1 analysis)				
Total dissolved solids, ppm	880	---	---	---
Boron, ppm	0.3	---	---	---
Effective salinity, epm	8.4	---	---	---

Data presented in the foregoing summary relative to the Fox Canyon aquifer, the Quaternary alluvium, and the San Pedro formation, although meager, suggest the quality of the waters derived from these deposits to be suitable for both irrigation and domestic use, at least in the southern and southeastern portions of the basin, where the wells producing from these deposits are located. The character of the water from these zones is generally calcium-sodium sulfate.

The quality of the waters derived from the Oxnard aquifer ranges from Class 1 to Class 3 for irrigation use. Some constituents, notably sulfate and total dissolved solids, exceed the recommended limits for domestic use published in Drinking Water Standards of the United States Public Health Service 1946[19]. Wells recently found to contain waters of high chloride content have not been considered, since these wells are believed to have been degraded by sea water entering the Oxnard aquifer near Port Hueneme. Sea-water intrusion is discussed in Chapter VI, entitled "Water Quality Problems".

Analyses of samples collected in 1931 from 27 wells producing from the Oxnard aquifer indicate that the average total dissolved solids content in that zone was about 850 ppm at that time. When this figure is compared to the 977 ppm average for 1952, it is apparent that there has been an increase in the salt concentration in the waters of this zone. The Oxnard aquifer is confined, as previously discussed, and is recharged primarily by subsurface movement from the Oxnard Forebay Basin. It is, therefore, not subject to quality fluctuations characteristic of free ground water aquifers which are recharged directly by deep penetrating rainfall and percolating surface waters of variable quality. It will, however, show an integrated reflection of changes in the Oxnard Forebay Basin, which is subject to variations in quality related to both time and hydrologic conditions. One hundred thirty-six analyses of water from 66 wells producing from the Oxnard aquifer and covering the period 1953 to 1956 are presented in Table H-9 of Appendix H. Except in the vicinity of Port Hueneme where sea-water intrusion is continuing, the analyses show no significant changes in quality or character. However, the trend of increasing salt concentration within this zone appears to be continuing.

The most important cation in the waters of the Oxnard aquifer is calcium generally followed by sodium, although certain wells, particularly in the area north of the City of Oxnard, yield waters with magnesium as the second most important cation. Sulfate is in nearly all instances the predominate anion, although a few wells located adjacent to the line delineated as the boundary between Pleasant Valley and the Oxnard Plain Basins, have sulfate concentrations of less than 50 per cent of the total anions with bicarbonate as the second most important anion. This is believed to be, at least in part, the result of pumping from a series of continuous or discontinuous lenses of water-bearing deposits recharged principally from the alluvial and Upper San Pedro deposits of adjacent Pleasant Valley Basin.

Studies relating the quality of water in the Oxnard aquifer with geographical location indicate that waters found in the area between the City of Oxnard and the Oxnard Forebay Basin and adjacent to the periphery of the Oxnard Forebay Basin are generally inferior in quality to those waters found in the balance of the aquifer. This may be seen from the data presented in the following tabulation.

Basin or aquifer	Total dissolved solids, ppm		Effective salinity epm	
	Average	Median	Average	Median
Oxnard Forebay	1269	1245	10.6	10.0
Oxnard Aquifer	977	914	8.1	7.4
Oxnard Aquifer near Forebay*	1280	1132	10.3	9.4

* Values based on 14 wells producing from Oxnard aquifer and located adjacent to Oxnard Forebay.

Recharge to the Oxnard aquifer is effected primarily through movement of water from the Oxnard Forebay Basin. The data indicates that the quality of the forebay area water is generally inferior to that in the Main Oxnard aquifer. It is apparent that some deterioration of the quality of the ground waters of the Oxnard aquifer has occurred, as previously discussed, and doubtless will continue to occur as a result of normal recharge.

It was previously mentioned that at shallow depth in the alluvial deposits of the Oxnard Plain Basin there exists a semiperched water-bearing zone which is recharged principally by deep penetration of rainfall and return irrigation water. Because of the extensive application of irrigation water, it has become necessary to install a tile drainage system in portions

of Oxnard Plain in order to maintain the water level below the root zone of crops. Analyses of samples of these semiperched waters, collected near points of discharge of drainage water, are presented in Table 10, entitled "Mineral Analyses of Drainage Water from Coastal Plain of Ventura County". The locations of sampling points used are delineated on Plate 7B.

Inspection of Table 10 will indicate that the waters of the semiperched body are similar in character to the waters derived from the Oxnard aquifer; however, they are Class 2 to Class 3 quality for irrigation use and generally unsuitable as a domestic supply. It is apparent that the semiperched ground water body represents a potential source of degradation to the valuable aquifers which underlie it. This water may gain access to the underlying deposits through improperly constructed or abandoned wells or through the lenticular sands and gravels which tend to increase the permeability of the cap. At the present time there is no direct evidence of degradation of the Oxnard aquifer by water of the semiperched body. However, it is suspected that waters from this source are contributing to the poor quality waters found adjacent to the zone of recharge and in the vicinity of well 1N/22W-11C2 which evidences high total dissolved solids and boron concentrations.

Analyses by Division of Water Resources except as otherwise noted.

a Analyzed by Pacific Chemical Consultants.

b Estimated.

c Ponded.

Pleasant Valley Basin. Ground waters of the Pleasant Valley Basin are derived from Recent and Pleistocene alluvium; the San Pedro formation, of which the principal aquifer is the Fox Canyon aquifer; and to a limited extent, the Santa Barbara formation and Miocene volcanics. The interpretation of the character and quality of the ground waters derived from each of these water-bearing deposits is difficult because of the widespread practice of multiple zone perforation of wells and the folding, faulting, and rapid thinning of formations.

To summarize the quality of the waters in the water-bearing deposits wherein data are available, there is presented in the following tabulation the maximum, minimum, average, and median values for total dissolved solids, boron, and effective salinity for a series of samples collected from 19 wells during the summer of 1952.

Chemical property	Maximum	Minimum	Average	Median
Quaternary Alluvium (7 analyses)				
Total dissolved solids, ppm	2878	746	2141	2458
Boron, ppm	1.5	0.3	0.7	0.7
Effective salinity, epm	25.2	5.5	18.4	20.6
San Pedro Formation (4 analyses)				
Total dissolved solids, ppm	1384	568	899	---
Boron, ppm	0.6	0.1	0.3	---
Effective salinity, epm	15.9	3.9	8.8	---
Fox Canyon Aquifer (7 analyses)				
Total dissolved solids, ppm	1492	460	1045	1282
Boron, ppm	0.6	0.0	0.3	0.3
Effective salinity, epm	14.9	3.0	10.3	12.7

The foregoing data show that, in general, the quality of the waters derived from the San Pedro formation and the Fox Canyon aquifer are Class 1 to Class 2 for irrigation purposes. However, certain constituents, notably sulfates and total dissolved solids, generally exceed the recommended limits for domestic use. Comparison of the quality of waters in relation to geographic location indicates that waters derived from the northern and eastern portions of the basin are generally of better quality than those extracted from the central and the southwestern parts.

Eighty ground water analyses from 50 wells in Pleasant Valley Basin covering the period 1953 to 1958 are presented in Table H-14 of Appendix H. These analyses show no significant changes in the general character or quality of the waters of this basin.

Available data indicate that the quality of the water obtained from deposits of Quaternary alluvium is generally unsuitable for domestic and/or irrigation use. Individual exceptions to this may occur, however, as evidenced by the analysis of well 2N/20W-33Q1 which produces water of good quality. Source of the poor quality water found in this deposit is obscure, but it appears probable that irrigation return is a factor.

The character of the ground waters of this basin varies widely, not only between aquifers, but within aquifers. Generally, the cation character is calcium-sodium, although several wells yield waters of a sodium-calcium character and a few waters show relatively high magnesium percentages. The predominant anion is usually sulfate, although sulfate-bicarbonate and bicarbonate waters are not unusual, particularly in the northern portion of the basin.

Comparison of the character of the ground waters of this basin

with respect to geographical location and direction of ground water movement, suggests the influence of inflow from Las Posas and Santa Rosa Basins on the character of ground water of Pleasant Valley. The influence of inflow from Santa Rosa basin is particularly noticeable because of the relatively high percentage of magnesium found in the waters from that basin. Over-all studies of ground water in Ventura County indicate that waters derived from volcanic formations nearly always contain a high percentage of magnesium. This characteristic provides a convenient indicator with which to trace the movement of waters emanating from volcanic formations. The influence of runoff from the volcanic formations which form the southeastern border of the basin is indicated by analyses of well 2N/20W-33Q1. While the character of water extracted from this well is similar to that emanating from Santa Rosa Basin, hydrologic conditions are such that the hills forming the southeastern border of the basin are the only possible source for water extracted from this well.

Calleguas Creek System

Ground water basins within the Calleguas Creek System include Simi, East and West Las Posas, Conejo, Tierra Rejada, and Santa Rosa Basins.

Simi Basin. The principal water-bearing deposits in Simi Basin are Recent and Pleistocene alluvium. Underlying and flanking the alluvium are semipermeable deposits which yield some water to wells. These include volcanics, the Sespe formation, the upper and lower Llajas formations, the Santa Susana-Martinez formation, and Cretaceous sandstones. In addition, considerable quantities of water are imported to the basin from Santa Barbara deposits found in Tapo Canyon which is within the drainage area tributary

to Simi Basin. The quality of the waters derived from each of these deposits, as indicated by analyses of samples collected in the summer of 1952, is suggested by the data presented in the following tabulation.

Source and chemical property	Maximum	Minimum	Average	Median
Quaternary Alluvium (18 analyses)				
Total dissolved solids, ppm	2,122	638	1,500	1,587
Boron, ppm	1.5	0.2	0.6	0.6
Effective salinity, epm	17.7	4.2	11.8	12.6
Cretaceous Deposits (3 analyses)				
Total dissolved solids, ppm	1,762	425	1,272	
Boron, ppm	0.3	<0.1	0.1	
Effective salinity, epm	20.1	5.6	13.2	
Sespe Formation (5 analyses)				
Total dissolved solids, ppm	1,061	340	737	670
Boron, ppm	0.1	0.0	<0.1	<0.1
Effective salinity, epm	8.6	2.2	5.4	5.2
Upper Llajas Formation (2 analyses)				
Total dissolved solids, ppm	1,548	727	--	--
Boron, ppm	0.3	0.0	--	--
Effective salinity, epm	16.7	6.9	--	--

Several water producing formations have been developed to only a limited extent. In four of these formations a single analysis is available, which will serve to indicate the quality to be expected. These analyses are presented in the following tabulation.

Formation	Total dissolved solids ppm	Boron ppm	Effective salinity, epm
Volcanic	625	<0.1	5.2
Martinez	747	0.1	7.1
Lower Llajas	1,750	0.9	19.4
Santa Barbara	600	<0.1	5.2

Eighty-nine additional ground water analyses from 55 wells in Simi Basin covering the period of 1953 to 1958 are presented in Table H-10 of Appendix H. These analyses show no general changes in quality or character in the ground waters from the Quaternary alluvium. However, seven analyses of waters from the Cretaceous deposits are available in Table H-10 and show better quality water than indicated by the average in the above summary.

Data in the above summary indicate that, while the quality of the waters derived from the alluvium ranges from Class 1 to Class 3 for irrigation use, the average and median values are of such magnitude that many of the waters may be unsuitable and should be used with caution on the more sensitive crops. Where possible, a larger than normal quantity should be applied to insure that soil solution concentrations do not become so great as to permit appreciable crop damage. The character of waters derived from the alluvium ranges from calcium sulfate to calcium-sodium sulfate, although a few analyses show magnesium as the second most important cation.

Studies relating the quality of the waters derived from the alluvium with respect to geographic location indicate a gradual increase in the salt content in the ground water from east to west. In general, the waters of poorest quality are found in the western portion of the basin, particularly in Section 8, T. 2 N., R. 18 W. As may be perceived from inspection of Plate 2, the general direction of ground water movement is from east to west, suggesting that the indicated deterioration is caused by concentration through re-use. Under

present conditions of deficient water supply in this valley it is anticipated that this condition will not only continue but become increasingly severe.

The situation is further complicated by the existence of a poor quality semiperched ground water body in a portion of the westerly end of the basin. This water body serves to prevent dispersion of the salts in irrigation return waters. While this protects immediately underlying water, it results in serious degradation at points where the semiperched water commingles with the principal ground water body in the alluvium. This effect is demonstrated by the very poor quality water found in Section 8, T. 2 N., R. 18 W, beyond the westerly extent of the semiperched body. The existence of the poor quality semiperched water indicates the necessity of careful well construction and abandonment within the areal extent of the semiperched water body to prevent further deterioration of the principal ground water body from this source.

There is a paucity of data relative to the quality of the waters derived from the older deposits which bound and underlie the alluvium. However, waters derived from the Sespe formation appear to be Class 1 and Class 2 waters and suitable for both domestic and irrigation use, at least within the limited depths from which water is extracted in this basin. The quality of water derived from the other formations ranges from Class 1 to Class 3 and varies widely in character between deposits. The effect of these variations is reflected in the seemingly erratic quality and character of water found in the eastern part of the basin. In this region many of the wells produce from both the alluvium and an underlying formation and it is believed that quality and character fluctuations reflect the influence of water from deeper formations.

In the latter part of the recent period of subnormal water supply, the water level in Simi Basin was lowered to such an extent that the alluvium was dewatered in part of the eastern area. For this reason, samples collected during this time may be considered representative of waters derived from deeper deposits. It appears that water pumped from Cretaceous deposits is of good quality, at least within the limited depths of wells in this valley, while the water derived from the Santa Susana-Martinez formation is variable in quality ranging from poor to good in quality.

There is evidence of dissolved hydrogen sulfide in waters extracted from six wells located in the southern and eastern parts of the basin. These wells, Nos. 2N/17W-9F1 and 9Q3, and 2N/18W-14D2, 15F1, 15J5, and 16G2, derive all or part of their supply from older deposits. The presence of the gas, together with lower than average sulfate content and higher than average bicarbonate concentrations, suggests the occurrence of sulfate reduction by bacteria of genus Desulfovibrio. The existence of this gas in concentrations normally found in water subjected to sulfate reduction has little effect upon its suitability for agriculture use, although it will impart a disagreeable taste and odor to the water.

The limited data available indicate that ground waters derived from the Santa Barbara formation in Tapo Canyon are of good quality and suitable for prevalent beneficial uses.

East and West Las Posas Basins. Ground water extracted for beneficial use in the Las Posas Basins is derived primarily from the Fox Canyon aquifer of the San Pedro formation. However, some water is also pumped from the Epworth gravels, an upper member of the San Pedro formation found primarily in the northern part of the basin; from the Grimes Canyon aquifer, which

underlies the Fox Canyon formation; and from the Quaternary alluvium. In addition minor amounts of water are produced from scattered lenses of sand and gravel distributed throughout the upper San Pedro formation.

A summary of the information obtained from a series of samples collected from wells in this basin during the summer of 1952 follows.

Source and chemical property	Maximum	Minimum	Average	Median
Quaternary Alluvium (8 analyses)				
Total dissolved solids, ppm	4927	755	2700	2772
Boron, ppm	2.4	0.1	1.3	1.9
Effective salinity, epm	50.9	6.0	25.4	25.2
Upper San Pedro Formation (10 analyses)				
Total dissolved solids, ppm	2530	225	1127	1202
Boron, ppm	1.3	0.1	0.4	0.4
Effective salinity, epm	24.9	1.2	10.1	11.5
Epworth Gravels (4 analyses)				
Total dissolved solids, ppm	255	206	228	--
Boron, ppm	0.1	0.1	0.1	--
Effective salinity, epm	1.4	1.0	1.2	--
Fox Canyon Aquifer (7 analyses)				
Total dissolved solids, ppm	1226	265	604	547
Boron, ppm	0.5	0.0	0.3	0.2
Effective salinity, epm	10.9	1.5	4.9	4.3
Grimes Canyon Aquifer (3 analyses)				
Total dissolved solids, ppm	1030	602	757	--
Boron, ppm	0.5	0.1	0.3	--
Effective salinity, epm	8.5	5.6	6.7	--

It is apparent from these data that the quality of the water produced from the Fox Canyon and Grimes Canyon aquifers and the Epworth Gravels is generally good, with average and median values well below

criteria established for both domestic and irrigation use. Conversely, water derived from the Quaternary alluvium appears to be of poor quality and generally unsuitable for most beneficial uses. The quality of water produced from the upper San Pedro formation ranges from Class 1 to Class 3 for irrigation use. It is noted that many of the wells, particularly those penetrating only to shallow depths in the formation, yield waters of good quality.

Thirty-seven analyses of ground water from 30 wells in the Los Posas Basins are available for the period of 1953 to 1958. These analyses show no significant changes in general quality or character of the ground waters. However, it is notable that 10 of 14 analyses of waters from the San Pedro formation showed total dissolved solids content of less than 700 ppm during this period.

The mineral character of water derived from the Epworth Gravels is generally calcium-sodium bicarbonate while the character of water produced from the Fox Canyon aquifer ranges from calcium bicarbonate in East Las Posas Basin to calcium-sodium bicarbonate-sulfate in West Las Posas Basin. It is noted however, that a majority of wells yield waters of calcium bicarbonate character. Waters derived from the Grimes Canyon aquifer range in character from calcium-sodium sulfate to sodium bicarbonate, while waters derived from the undifferentiated San Pedro formations vary rather widely in character from calcium sulfate to calcium-sodium bicarbonate. Waters derived from the alluvium are generally calcium sulfate to calcium-sodium or calcium-magnesium sulfate in character. With minor exceptions, the bicarbonate anion character indicated above is peculiar to basins in the Calleguas Creek system, with the result that the influence of ground waters moving from the Las Posas Basins or the character of the ground waters of the northwestern portion of Pleasant

Valley Basin is readily discernable.

Studies relating the quality of waters from each of the aquifers or formations on an areal basis revealed little significant information. However, the wide difference in quality between the waters of the Quaternary alluvium and those derived from deeper formations indicates the necessity for the promulgation and utilization of adequate standards for well construction and abandonment.

Santa Rosa Basin. Ground water of Santa Rosa Basin is derived from three formations: Recent alluvium, Miocene volcanics, and the San Pedro formation. The latter formation can be divided into two parts, one of which is probably the equivalent of the Fox Canyon aquifer, which may be traced in the western portion of the valley. The other part is generally silty and is found throughout the central and eastern portion of the valley. The silty deposits include lenses of sand and gravel which contain extractable ground water.

Data tabulated below from a series of samples collected during the summer of 1952 indicate the general quality of the waters derived from each of the three water-bearing formations.

Source and chemical property	Maximum	Minimum	Average	Median
San Pedro Formation (7 analyses)				
Total dissolved solids, ppm	842	552	644	608
Boron, ppm	0.4	0.1	0.2	0.1
Effective salinity, epm	5.8	3.2	4.7	4.3
Volcanic Formation (4 analyses)				
Total dissolved solids, ppm	658	528	583	--
Boron, ppm	0.6	0.1	0.3	--
Effective salinity, epm	7.7	3.8	5.1	--

Source and chemical property	Maximum	Minimum	Average	Median
Recent Alluvium (1 analysis)				
Total dissolved solids, ppm	719	--	--	--
Boron, ppm	0.6	--	--	--
Effective salinity, epm	6.2	--	--	--

The data indicate that ground waters of Santa Rosa Basin are of good quality and suitable for prevalent beneficial uses. The most important cation in nearly all of the ground water of this valley is magnesium, and in nearly all instances the predominant anion is bicarbonate.

Twenty-two additional analyses of ground water from 12 wells within this basin are available covering the period 1953 to 1958 and are presented in Table H-13 of Appendix H. These analyses show no significant changes in water quality or character.

Tierra Rejada Basin. Ground water in the Tierra Rejada Basin is derived almost entirely from highly fractured volcanic rock. Available analyses indicate water produced from these rocks to be of excellent quality and suitable for prevalent beneficial uses. The maximum total dissolved solids concentration is less than 800 parts per million, effective salinities are generally less than 5 epm, and the boron content is less than 0.4 ppm. The character of ground water is magnesium-calcium bicarbonate, illustrating the high magnesium percentage typical of water derived from volcanic formations in Ventura County.

Conejo Basin. Ground water in Conejo Basin is principally derived from fissures and weathered zones in the volcanic rock, although water is also produced from older sedimentary formations, such as the Modelo and Topanga sandstones and shales. The alluvium in this basin is very

thin and not considered significant as a source of ground water.

The quality of waters extracted from the volcanic, Topanga, and Modelo formations is presented in the following summary, based upon samples collected in June and July, 1952.

Source and chemical property	Maximum	Minimum	Average	Median
Volcanic Formation (11 analyses)				
Total dissolved solids, ppm	1118	353	631	511
Boron, ppm	0.2	0.0	0.1	0.1
Effective salinity, epm	10.9	2.0	5.1	4.3
Modelo Formation (4 analyses)				
Total dissolved solids, ppm	2064	726	1344	--
Boron, ppm	0.2	0.1	0.1	--
Effective salinity, epm	21.1	5.9	13.2	--
Topanga Formation (2 analyses)				
Total dissolved solids, ppm	1355	404	--	--
Boron, ppm	0.1	0.0	--	--
Effective salinity, epm	12.0	2.8	--	--

The data indicate that, in general, water extracted from the volcanic formation is of good quality and suitable for the prevalent beneficial uses. The quality of waters produced from the other formations appears to vary from Class 1 to Class 3 for irrigation purposes, but data available are too meager for accurate evaluation.

Seventy-one analyses of ground water from 40 wells within Conejo Basin covering the period 1953 to 1958 are presented in Table H-15 of Appendix H. These analyses show large variations in quality of waters extracted from each of the producing formations and no significant changes in character or quality.

The character of ground water produced from the volcanic formation generally ranges from magnesium-calcium bicarbonate to calcium-magnesium bicarbonate. The character of waters derived from the Modelo and Topanga formations varies from calcium-magnesium bicarbonate to magnesium-calcium sulfate, with the poorer quality waters usually being calcium sulfate in character.

In this basin the preponderance of poorer quality water is found in the vicinity of Section 2, T. 1 N., R. 19 W., where water is derived from the Topanga and Modelo formations.

Malibu Creek System

Information concerning ground water quality in this drainage system is limited to analyses of samples collected from a few of the wells drilled in Hidden and Russell Valleys. The scarcity of available data permits only a general evaluation of the quality and character of the ground waters.

Ground waters of Hidden Valley are derived primarily from fissures in volcanic rocks and from overlying alluvium. The quality of ground water appears to be good, with total dissolved solids concentrations less than 800 ppm, effective salinity values less than 6 epm, and boron concentrations less than 0.5 ppm. The character usually varies from calcium bicarbonate to calcium-magnesium bicarbonate.

Ground waters of Russell Valley are produced from alluvium, volcanic, Topanga, and Modelo formations. These waters range in quality from Class 1 to Class 3 for irrigation use, with total dissolved solids concentrations ranging from about 400 to 2600 ppm, and effective salinity values ranging from about 2.5 to over 26 epm. Insufficient data are available to enable differentiation of the quality of water from different deposits or to determine sources of poor

quality waters. The character of ground water in this valley varies from sodium bicarbonate to calcium-magnesium sulfate.

Quality of Prospective Imported Supplemental Supplies

On the basis of presently planned future water supply development in California, there are two possible sources from which a supplemental water supply could be imported into Ventura County. These sources are the Colorado River, from which water could be imported through facilities of The Metropolitan Water District of Southern California, and surplus waters from northern California to be conveyed in the facilities of the authorized Feather River Project of the State of California.

Colorado River Water

Either natural or softened Colorado River water could be imported into Ventura County, depending on the location of the connection made to the Metropolitan Water District System. The mineral quality of the treated and natural waters is indicated by the analyses presented in Table 11, entitled "Mineral Analyses of Natural and Softened Colorado River Water". These data indicate that the natural waters have sodium-calcium sulfate character similar to that of many waters of Ventura County, particularly in the Santa Clara River valley, and are of better quality than most of the ground water in Ventura County. The softened water is sodium sulfate in character, with a total dissolved solids concentration nearly the same as that for the unsoftened water. The softened water has a high sodium percentage and would therefore be less desirable for prolonged irrigation of certain crops.

TABLE 11

MINERAL ANALYSES OF NATURAL AND SOFTENED COLORADO RIVER WATER[a]

Type	ECx10^6 at 25°C	pH	Mineral constituents in parts per million											Total dissolved solids: ppm	Effective Salinity: epm	Percent sodium
			Ca	Mg	Na	K	CO_3	HCO_3	SO_4	Cl	NO_3	B	F			
Natural	1,260	8.4	96	35	121	5	1	146	364	109	1.1	0.16	0.4	815	8.28	40
Softened	1,335	8.5	36	14	225	5	4	126	364	114	0.8	0.16	0.4	836	10.28	76

a. Data obtained from 19th Annual Report Metropolitan Water District of Southern California. Analyses represent average for period July 1, 1956 to June 30, 1957.

San Joaquin Valley - Southern California Aqueduct System

The San Joaquin Valley - Southern California Aqueduct System authorized by the Legislature in 1951 provides, among other things, for the export of surplus waters available in the Sacramento-San Joaquin Delta to areas of deficiency in southern California. Water will be transported to the San Luis Reservoir for storage and regulation prior to delivery to the San Joaquin Valley service area and to southern California.

A study of the mineral quality of water which may be expected under the most adverse conditions has been made. In this study, an evaluation of the effect of the San Luis Reservoir water to be delivered south has been made. These studies reflected the effect of evaporation losses in the reservoir but canal losses were assumbed to be negligible. As a result of these detailed studies, it was found that the water to be delivered to southern California under the most adverse conditions would not exceed a mean monthly value of 300 ppm total dissolved solids, 40 ppm chlorides, and 150 ppm total hardness. The mean annual value of water diverted for use in southern California based on the mean of an historic eight-year drought period is 200 ppm total dissolved solids, 30 ppm chloride, and 100 ppm total hardness. The mineral character of the water will be calcium bicarbonate with each constituent less than 100 ppm. Detailed information on recommended limits for other constituents is presented in Chapter III of Bulletin No. 3, "The California Water Plan", State Department of Water Resources, May, 1957.

On the basis of these studies, it is apparent that northern California surplus waters planned for export to southern California will be of

better mineral quality than any of the existing water supplies in Ventura County The cation character will be calcium similar to most of the waters in Ventura County. The anion character, however, is bicarbonate as opposed to sulfate which is predominate in most of the water supplies in Ventura County. This difference should not cause or create any problems or difficulties upon mixing.

Quality of Tidal Waters

Tidal waters in Ventura County consist almost entirely of saline waters from the Pacific Ocean. The mineral quality of these waters is typified by the following analysis of a sample collected from the ocean near the intersection of West 5th Street and Beach Road, Ventura County, in May, 1953.

Cations	epm	ppm	Anions	epm	ppm
Ca	20.3	406	HCO_3	2.4	148
Mg	108.5	1,318	SO_4	55.3	2,650
Na	466.0	10,700	Cl	535.0	19,000
K	10.5	408	NO_3	0.2	12
			Boron	--	3.8

Total dissolved solids ppm 34,766

The mineral quality of tidal waters is affected by high flood flows in the Ventura and Santa Clara Rivers and Calleguas Creek. The effect of such flows, however, is temporary and limited in extent.

Tidal waters receive oil brine wastes near the mouth of the Ventura River, cannery wastes in Hueneme Harbor and combined industrial wastes carried in the industrial outfall at Oxnard. The volume of these industrial

wastes is such that their effect upon the mineral quality of tidal waters is negligible.

Sanitary wastes are discharged to the ocean, via ocean outfalls, by the cities of Ventura and Oxnard, the Port Hueneme Sanitary District, and the U. S. Naval Construction Battalion Center at Port Hueneme. Sanitary wastes from the U. S. Naval Air Missile Test Center are discharged into tidal waters of Mugu Lagoon. The effect of these discharges on the mineral quality of tidal waters is insignificant but their effect upon sanitary quality is important. The Los Angeles Regional Water Pollution Control Board has adopted waste discharge requirements for all discharges except those by the naval installations. At this time the discharges to tidal waters do not appear to have adversely affected beneficial uses. However, as the population grows and larger areas are sewered, the discharges of wastes to tidal waters will increase, with attendant pollution problems.

Summary

During periods of high flow, the quality of waters in the surface streams of Ventura County is generally suitable for nearly all beneficial uses. However, during periods of relatively low flow, certain of these streams contain sufficient concentrations of total dissolved solids, or of a particular constituent, notably boron, to render them marginal or unsuitable for some uses. Streams which contain high concentrations of total dissolved solids include Canada Larga, Hopper Creek, Santa Clara River near Blue Cut, Arroyo Simi, and Tapo Creek. Streams which contain high concentrations of boron during low flow periods include Matilija, Sespe, and Piru Creeks.

The quality of ground water derived from Recent and Pleistocene deposits in Ventura County ranges from suitable to unsuitable, with the preponderance of the waters becoming of marginal quality for prevailing beneficial uses during periods of below normal water supply. For domestic, municipal, and industrial uses the ground waters are, almost without exception, "very hard". Waters of good mineral quality are generally produced from the Miocene volcanics in Conejo, Tierra Rejada and Santa Rosa Basins. Waters derived from normally semipermeable Tertiary deposits, which are capable of yielding only minor quantities of water, are generally of very poor quality and contain high concentrations of calcium and sulfate.

In areas where antecedent data are available, it is indicated that the quality of ground water has deteriorated measurably during the past 20 years. In nearly all of the 17 ground water basins in Ventura County there are areas of good quality water and areas of very poor quality water. There are notable areas of good quality water in Conejo, Los Posas, Ojai, Santa Rosa, and Tierra Rejada Basins. Specific areas where the quality of ground water is such that it is essentially unusable include the Recent alluvial deposits of the Lower Ventura River Basin and the semiperched ground water body of the Oxnard Plain Basin. Poor quality waters in other basins range from marginal to completely unsuitable. The extent of such poor quality water, however, is usually confined to localized areas.

CHAPTER VI. WATER QUALITY PROBLEMS

Deleterious effects on the quality of water are generally manifested as a consequence of surface and ground water deficiencies, lack of drainage, and improper disposal of wastes. Problems of water quality are common to nearly all other water problems. In order to provide for the maximum beneficial uses of the available water supplies, thus minimizing the necessity for the importation of costly supplies from other areas of the state, it is necessary that every practicable effort to maintain the existing quality of locally available waters be made.

Man's development has characteristically exerted an adverse effect upon the native quality of waters. Most uses of water by man, for irrigation, for instance, as well as for the disposal of sewage and industrial wastes, add pollutants to the waters with resultant deterioration in quality. Hence, as these uses increase, the necessity for adequate treatment and disposal of waste waters becomes increasingly imperative if the quality is to be maintained at satisfactory levels for the higher beneficial uses. This is particularly true in areas of deficiency, for the quality of imported waters must be maintained at sufficiently high levels to permit necessary re-use.

In numerous coastal ground water basins normally containing fresh water, overdraft conditions have resulted in the intrusion of sea water into the aquifers, the natural underground formations which store and transmit water. This has been caused by reversal of the natural seaward ground water gradient due to excess of pumped extractions over the natural ground water replenishment. The restoration of basins which have

been lost to sea-water intrusion, or to any other type of impairment, will be a long process - if possible at all. Saline water must be physically removed, either by pumping or by maintenance of favorable gradients for an extended period.

Potential sources of quality degradation from deep connate brines and adverse salt balance also exist. Connate brines are ocean waters that were trapped in ground water basins which were inundated in past geologic periods.

Salt balance refers to that desirable condition wherein the amount of soluble salts entering a basin is balanced by the amount of salts leaving a basin, either by natural disposal, sewage outflow, or by pumping for export. The extent of adverse salt balance in ground water basins is not known at the present time, due to the lack of long-term records of mineral analyses.

In the process of drilling and altering wells, improper methods are being employed in many instances. Such practices may result in an inadequate seal between strata of usable and unusable waters, thus allowing interchange, and degradation or pollution of ground water. Lack of adequate surface seals may permit inflow of inferior surface waters with consequent damage to ground water quality. Likewise, failure to seal abandoned wells, or improper sealing when attempted, may result in pollution of ground water. These problems are rapidly becoming more serious as older well casings deteriorate and are abandoned and the drilling of new wells continues at an unprecedented rate.

Disastrous results may be caused by disposal of inadequately treated sewage and industrial wastes to streams and to ground water basins. Waste disposal problems may arise not only from liquid-borne wastes but also from disposal of garbage, refuse, and industrial wastes. Every effort must be made

to maintain the quality of available waters by appropriate planning for, and control of, the treatment and disposal of wastes, giving consideration to the effect of such waste disposal upon future planned uses as well as the present uses of the receiving waters. To this end the Legislature in 1949 created the State and 9 Regional Water Pollution Control Boards to exercise authority over the disposal of wastes.

Problems of water quality may be broadly classified as resulting from (1) degradation from natural causes, or (2) impairment as the result of cultural development. This chapter discusses the various sources of impairment and degradation which have altered or may, in the future, affect the mineral quality of surface and ground waters of Ventura County.

Degradation from Natural Sources

Degradation from natural sources results in the deterioration of surface and ground water supplies through the introduction and commingling of native waters of poor quality. In Ventura County, such poor quality waters usually exist in marine sedimentary deposits of Tertiary age or older. Because of the tightness of the older soils and formations, these deposits have not been entirely leached of the more soluble salts. In some instances, these waters may be connate waters which have been released by changes in hydrologic or geologic conditions.

Surface and ground waters in Ventura County have been subjected to degradation by natural sources in many instances. Boron concentration in the low flow of several streams is above the safe limit for irrigation use on highly sensitive crops. Several of the smaller creeks and streams in Ventura County discharge waters containing high salt concentrations, particularly during periods of low flow.

Basins where ground water has been degraded by poor quality waters from natural sources include Upper Ojai, Piru, Fillmore, and Santa Paula Basins. There are three wells in the eastern end of Upper Ojai Basin which have been degraded by high chloride waters. In Piru Basin, in the vicinity of the mouth of Piru Creek, ground waters occur which contain high concentrations of boron. To the south of Piru, Fillmore, and Santa Paula Basins, there are wells which apparently have been degraded by ground waters moving from the older formations bounding these basins. In addition, it seems probable that some degradation of ground waters in nonpressure areas has occurred as a result of deep percolation of poor quality waters near the mouths of the numerous small streams.

Impairment as a Result of Cultural Development

In the normal processes of day-to-day living in any developed area, wastes which may have a degrading effect on the quality of surface and ground waters are produced. These wastes include irrigation return water, effluents from industrial operations, sewage, and miscellaneous wastes produced by the population inhabiting the area. Continued pumpage and utilization of water from ground water basins may result in adverse salt balance. Intrusion of saline ocean water may occur in aquifers outcropping under the sea if piezometric levels are depressed below sea level for protracted periods.

Irrigation Return Water

Evaporation and transpiration consume much of the water applied to irrigated crops with little or no effect on the quantity of dissolved minerals originally contained in the water. As a result, the portion of applied water

which percolates below the root zone contains a higher concentration of dissolved minerals than the water from which it was derived. It has been estimated that the salt concentration in this residual water ranges from two to over eight times that in the water originally applied. This effect prevails despite the precipitation of certain salts, as described in Appendix F, "Evaluating the Quality of Irrigation Waters in Ventura County".

In Ventura County, where large land areas are devoted to irrigated agriculture, the percolation and commingling of irrigation return water with underlying ground water supplies can result in appreciable degradation of the over-all quality of the ground water. Derivation of the magnitude of such degradation involves determination and analysis of a large number of variables. Intensive studies leading to definition and solution of the intricate chemical relationships involved are presently being accomplished by the Department of Water Resources. The over-all effect of the numerous known or suspected sources of degradation are described by using the concept of salt balance, as discussed later in this chapter.

In basins where free ground water table conditions prevail, such as Piru, Fillmore, and Ojai Basins, irrigation return water percolates directly to, and commingles with, the underlying ground water. Degradation attributable to this source is, therefore, fairly evenly distributed over the basin. Its effect is usually recognizable as a gradual increase in the salt concentrations of ground waters as they move downstream under the prevailing hydraulic gradient.

In areas where semiperched bodies of water occur, as on the Oxnard Plain and in Pleasant Valley, Simi, and Las Posas Basins, irrigation return water percolates to a semiperched water zone and remains as a

body of poor quality water which may affect underlying aquifers containing waters of better quality. Degradation of good quality water may occur by slow percolation through tight materials underlying the semiperched zone, movement around discontinuous clay lenses which support the semiperched zone, and/or interconnection of aquifers through broken well casings, improperly constructed or abandoned wells, or gravel-packed wells.

Ground water basins in Ventura County wherein degradation is considered to have occurred as the result of the downward migration of irrigation return water include Oxnard Plain, Santa Paula, Mound, Simi, and Conejo Basins. In Santa Paula Basin three wells yield water which may have been degraded by poor quality semiperched water migrating to the principal aquifer, apparently through casing leaks in the wells.

In the Oxnard aquifer of the Oxnard Plain Basin, ground waters between the City of Oxnard and the Forebay Basin, and on the periphery of the Forebay Basin, are generally inferior in quality to those waters found throughout the balance of the aquifer. It appears that this inferior quality may be due to the downward movement of semiperched water through the clay cap. Interconnection of aquifers by wells improperly constructed or abandoned may also contribute to the degradation of the water in the Oxnard aquifer.

Ground waters in the alluvium of the western part of Simi Valley appear to have been degraded by semiperched waters moving downstream from a limited pressure area which exists in this basin. It also seems possible that poorly constructed or abandoned wells have allowed ingress of poor quality semiperched water at other points in the pressure portion of this basin. Some deterioration from irrigation return water may also have occurred in the older Topanga and Modelo formations which occur in Conejo Basin.

From the foregoing discussion it is apparent that wells improperly constructed or abandoned and wells with leaky casings are providing a convenient route through which semiperched waters may migrate to and deteriorate the mineral quality of important ground water aquifers in Ventura County. It appears that appropriate action should be taken to establish standards for the construction and abandonment of wells in areas where interconnection of aquifers may result in degradation of ground waters.

Sewage

Sewage is defined in the Water Code as "any and all waste substance, liquid or solid, associated with human habitation, or which contains or may be contaminated with human or animal excreta or excrement, offal, or any feculent matter". The organic increment normally associated with sewage can be readily reduced or removed by treatment. However, the contribution of dissolved mineral salts resulting from the utilization of water for domestic purposes is not removed by ordinary treatment processes. According to Publication No. 9 of the California State Water Pollution Control Board, entitled "Waste Water Reclamation and Utilization", the increment of total dissolved solids contributed to domestic sewage will, on the average, range from 100 to 300 ppm. In areas where sewage treatment and disposal facilities result in planned or incidental recharge to ground water, some deterioration in ground water quality will undoubtedly occur.

The principal sewage treatment plants in Ventura County are listed in Table 12, entitled "Sanitary Sewage Treatment Plants, Ventura County", together with pertinent information concerning plant facilities, method and volume of discharge, and effect on receiving waters. The

locations of the various plants are delineated on Plate 12, entitled "Oil Fields and Waste Discharge Locations". Mineral and sanitary analyses of the plant effluents are presented in Table D3 of Appendix D.

The Los Angeles Regional Water Pollution Control Board has prescribed waste discharge requirements for all sewage treatment plants except the City of Ventura and the United States naval installations. In all cases where discharges are to land the Board has also prescribed ground water monitoring programs to determine the effects of the discharges on receiving waters.

TABLE 12

SANITARY SEWAGE TREATMENT PLANTS,

Port Hueneme Sanitary District	Domestic sewage	6,900	0.70[b]	780	Screening, primary sedimentation, sludge digestion, chlorination	Pacific Ocean	None
Point Mugu Naval Station	Domestic sewage	--	0.13[e]	150	Primary sedimentation	Mugu Lagoon to Pacific Ocean	None
City of Fillmore	Domestic sewage and industrial waste	2,805	0.30[d]	340[d]	Comminution, primary and secondary clarification, trickling filtration, percolation ponds.	Percolation ponds adjacent to Santa Clara River	No apparent degradation to surface or ground waters.
CALLEGUAS CREEK DRAINAGE SYSTEM							
Camarillo State Hospital	Domestic sewage	7,000	0.75[c]	840	Primary sedimentation, trickling filtration, secondary sedimentation, sludge digestion and chlorination.	Holding pond to Pleasant Valley Basin to irrigation or Calleguas Creek.	No apparent degradation to surface or ground waters.

a. Obtained from report to County of Ventura "Ventura County Waste Disposal Study" - May, 1958.
b. Estimate by discharging agency.
c. Estimate by Los Angeles Regional Water Pollution Control Board.
d. Based on servicing of 60% of population and .05 MGD industrial load.
e. 1954-55 data.

As stated, domestic use of water adds on the average between 100 and 300 ppm total dissolved solids. The estimated incremental quantities of salts, in sewage annually discharged in such a manner that it can percolate to economically important ground water bodies in the Ventura River, Santa Clara River, and Calleguas Creek systems, are presented in the following tabulation. In the instance of sewage treatment plants, discharge volumes based upon metered flows were used where available. In other areas, estimates were based upon the average increment, average sewage disposal of 70 gallons per capita per day and population estimates as obtained from a report to the County of Ventura entitled "Ventura County Waste Disposal Study".

Source of discharge	Estimated quantity of salts discharged tons per year	
	Minimum	Maximum
Ventura River System Above Foster Park		
Ojai Sewage Treatment Plant	50	145
Cesspools and septic tanks	45	135
TOTALS	95	280
Santa Clara River System Above Oxnard Plain Basin		
Santa Paula Sewage Treatment Plant	150	450
Saticoy Sanitary District Sewage Treatment Plant	25	70
Fillmore Sewage Treatment Plant	45	140
Cesspools and septic tanks	355	1065
TOTALS	575	1725
Calleguas Creek System		
Cesspools and septic tanks	135	400
TOTALS	135	400

It is apparent from the foregoing tabulation that, in the areas considered, discharges to cesspools and septic tanks constitute the principal metho of disposal of sewage. While the over-all effect of these disposals is certain to result in deterioration of ground water, it is considered that the individual effect of discharges to private disposal systems on the mineral quality of receiving waters is of minor significance. On the other hand, the concentration of effluent discharges from community sewage treatment plants may have a noticeable effect upon ground water in the vicinity of the discharge.

The only sewage treatment plants in Ventura County discharging large quantities of sewage effluent to streams or percolation ponds are the Cities of Fillmore, Ojai, and Santa Paula, the Saticoy Sanitary District, and the Camarillo State Hospital. The discharges of the Cities of Ojai and Santa Paula, the Saticoy Sanitary District, and the Camarillo State Hospital were investigated and memorandum reports were made to the Los Angeles Water Pollution Control Board (No. 4) in June and July, 1954. As of the date of survey, it did not appear that degradation of ground water had occurred as a result of these discharges. In the Santa Paula and Ojai Basins, however, recent mineral analyses of ground water indicate that mineral concentrations have increased in ground waters below the effluent disposal site. It is probable that the higher concentrations of dissolved salts are due, at least in part, to discharges from these plants.

A memorandum report was also made in March, 1955, to the Los Angeles Water Pollution Control Board (No. 4) concerning the proposed waste discharge from the City of Fillmore sewage treatment plant. The effects of this discharge on the receiving waters are not yet known.

Industrial Waste

The production, manufacture, or processing of many marketable goods results in the production of waste materials or solutions requiring disposal. In some instances, industries by means of reprocessing can evolve a marketable product from such wastes. In the majority of cases, however, disposal of the waste is made by the most convenient and economical means available, commensurate with public welfare.

The mineral quality of wastes may range from innocuous wastes containing little, if any, dissolved or water soluble salts to wastes containing acids, caustics, toxic substances or high concentrations of minerals. Where these latter wastes are disposed to land, especially in areas where movement to surface streams or percolation to economically important ground water bodies may occur, pollution or contamination may result. In areas such as Ventura County, where the quality of much of the water supply is marginal, the addition of such wastes may ultimately render the water supply unfit for domestic or irrigation use.

Industries in Ventura County which produce waste containing relatively high concentrations of dissolved minerals include the petroleum industry and citrus, walnut, and vegetable processing and packing plants. Other sources of degradants are the by-products of the regeneration of industrial and domestic water softeners,and salts leached from industrial and domestic wastes which have been deposited in dump sites. The methods of disposal and their effect on water supplies have been the subject of investigations and reports by the former Division of Water Resources and the Los Angeles Regional Water Pollution Control Board (No. 4). In the

paragraphs to follow there is presented a summary of information found as a result of these surveys and such additional data as were gathered in the course of the investigations for this report.

Oil Industry. One of the major industries in Ventura County is the extraction of oil from subterranean formations. Coincident with this extraction, a waste water which usually contains high concentrations of dissolved minerals and small quantities of oil is obtained. Newly drilled oil wells generally have a low production of brines in relation to their oil production. However, as a well or a field grows older, the brine production generally increases and oil production decreases. According to figures obtained from the State of California, Division of Oil and Gas, oil production from the 15 oil fields of Ventura County during the period July 1, 1951, to June 30, 1952, exceeded 37 million barrels. Waste production for the same period was estimated to exceed eight million barrels.

In an investigation of oil waste disposal practices in Ventura County for the Los Angeles Regional Water Pollution Control Board, it was found that ultimate disposal of oil field waste waters could be made to the Pacific Ocean, to injection wells, or to sumps or stream channels. When properly controlled, the first two disposal practices cause no pollution of fresh or saline waters. The disposal of oil field waste waters to permeable stream channels or to unlined sumps can be a serious pollution hazard to both surface and ground water.

Statistical data respecting discharges are summarized for each of the oil fields in Ventura County in Table 13, entitled "Summary of Oil Waste Disposal Data, Ventura County". Disposal practices, areas of disposal, and effects on receiving waters are summarized in Table 14, entitled "Oil Waste Disposal Practices, Ventura County". Typical mineral analyses of oil brines are presented

in Table 15, entitled "Typical Mineral Analyses of Oil Field Waters, Ventura County". These water data indicate the highly mineralized character of the waste.

In the report entitled "Ventura County Oil Waste Investigation", June, 1954, prepared for the Los Angeles Regional Water Pollution Control Board by the former Division of Water Resources, it was estimated that the brine disposed of annually contained approximately 27,400 tons of salt. It was concluded that the disposal of oil field waste waters in the South Mountain, Sespe, Bardsdale, Piru, Temescal, and Simi Oil Fields and the unconfined discharges and spill from sumps in portions of the Ventura Avenue, Ojai, and Santa Paula Oil Fields constituted a threat of pollution to ground waters in Ventura County.

Acting on the data and conclusions reached in these reports the Regional Board took immediate steps to correct discharge practices which were considered as a source of pollution or a threat of pollution. In virtually all cases improper waste disposal practices were voluntarily corrected by the industry. Wherever appropriate, waste discharge requirements have been prescribed by the Regional Board.

TABLE 13

SUMMARY OF OIL WASTE DISPOSAL DATA, VENTURA COUNTY[a]

Oil field	Number of sumps as of August 1952		Total area of active unlined sumps, in square feet	Number of unconfined discharges	Brine production for period July, 1951, to June, 1952, inclusive, in barrels[b]	Estimated salts in brine produced, in tons
	Total	Active				
Rincon	58	48	266,500	12	1,682,600	6,655
San Miguelito	14	9	21,500	4	270,600	1,139

a. Data from First Progress Report on "Ventura County Oil Waste Investigation", May, 1952, (3) and "Ventura County Oil Waste Investigation", June, 1954.(4)

b. Equal to 42 gallons.

c. Less than 0.5 tons.

TABLE 14

OIL WASTE DISPOSAL PRACTICES, VENTURA COUNTY

Name of oil field	Waste material	Disposal practices	Drainage areas	Effects on receiving waters
Rincon	Oil, waste water, asphalt, and drilling mud	Discharge to small water courses, thence to ocean	Pacific Ocean	No threat of pollution if oil removal is complete
San Miguelito	Oil, waste water, asphalt, and drilling mud	Discharge to small water courses, thence to ocean	Diablo Canyon and Pacific Ocean	No threat of pollution if oil removal is complete
Ventura Avenue	Oil, waste water, asphalt, and drilling mud	Seepage sumps, unconfined discharges, and joint salt water disposal line	Sexton, Harmon, Hall, San Joaquin, and Lake Canyons, Diablo Creek, Ventura River, and Pacific Ocean	Ground water in lower Ventura River have been degraded beyond use since 1926
Ojai	Oil, waste water, asphalt, and drilling mud	Seepage sumps, injection, unconfined discharges, evaporation, and hauling	Weldon Canyon, Sisar, Santa Paula and San Antonio Creeks, and Ventura River	Threat of pollution to Sisar Creek
Santa Paula	Oil and waste water	Seepage sumps, and unconfined discharges (prior to 1953)	Anlauf, Timber, Wheeler, and Adams Canyons, and Santa Paula Creek	Possible source of pollution to surface and ground waters of Santa Paula Basin
South Mountain	Oil, waste water, asphalt, and drilling mud	Seepage sumps, unconfined discharges	Willard, Morgan Richardson, Fox and Coyote Canyons and Santa Clara River	No apparent threat of pollution
Sespe	Oil and waste water	Seepage sumps and unconfined discharges	Sespe and Tar Creeks and Pole Canyon	Direct discharges to Sespe Creek and seepage sumps are polluting the surface and ground waters of Sespe Creek and Santa Clara River Valleys

OIL WASTE DISPOSAL PRACTICES, VENTURA COUNTY
(continued)

Name of oil field	Waste materials	Disposal practices	Drainage areas	Effects on receiving waters
Bardsdale	Oil, waste water, asphalt and drilling mud	Seepage sumps, unconfined discharges, and flood injection	Grimes, Shiells and Calumet Canyons, and Santa Clara River	Threat of pollution to * ground water of Fillmore Basin adjacent to the mouth of Grimes Canyon
Piru	Oil, waste water, and drilling mud	Seepage sumps, unconfined discharges, flood injection (Tapo Canyon), and direct discharges to Piru Creek	Hopper, Torrey, North Tapo, Modelo, and Eureka Canyons, and Piru Creek	Threat of pollution to * Hopper Canyon Creek and to surface and ground waters of Piru Creek and Santa Clara River Valleys
Temescal	Oil, waste water, and drilling mud	Seepage sumps and unconfined discharges	Lime Canyon and Piru Creek	Threat of pollution to * surface and ground waters of Piru Creek and Santa Clara River Valleys
Ramona	Oil, waste water, and drilling mud	Seepage sumps and flood injection	Holser and San Martinez Grande Canyons	Source of pollution to * the ground waters of Santa Clara River Valley
Simi	Oil, waste water, and drilling mud	Seepage sumps	Brea and South Tapo Canyons	Source of pollution to useable ground water in Simi Basin
West Montalvo	Waste water	Seepage sumps	Ocean	None
Oxnard	Oil, asphalt, tar and waste water	Seepage sumps and unconfined discharges	Ocean	None
Conejo	Oil and waste water	Seepage sumps	Conejo Creek	None

a. Data from "First Progress Report on Ventura County Oil Waste Investigation," May, 1952 (3), and "Ventura County Oil Waste Investigation," June 1954 (4).
b. Total dissolved solids by summation.

Citrus Packing Plants. In order to inhibit spoilage, citrus fruit is washed, cleaned, given fungicidal treatment, and a final rinse prior to packing for shipment. Agents commonly used in this treatment are "Red Star Crystals", soap, borax, soda ash, sodium hypochlorite, or "Decco". These agents may be used alone or in combination.

Wastes from citrus packing plants consist of water mixed with the various chemical agents used to facilitate washing and fungicidal treatment. Discharges consist primarily of dumping of the final rinse tanks and occasional draining of washing tanks. Mineral analyses of various types of packing plant wastes are presented in Table 16, entitled "Mineral Analyses of Citrus Packing Plant Wastes". The data in this table reveal a considerable variation in the chemical composition of the different types of wastes. Total dissolved solids range from over 24,000 ppm for borax treatment to 2,700 ppm for "Decco" treatment. The pH ranges from 1.8 for "Decco" waste to over 10 for combinations of soap and "Red Star Crystals". It is noted that all of the wastes with the exception of that from the "Decco" treatment contain high concentrations of boron and a high percentage of sodium. Boron concentrations exceeding one part per million have an adverse effect on boron sensitive crops, and the effect of sodium degradation can assume widespread proportions. It is apparent that packing plant wastes have a serious potential effect upon the quality of ground water.

TABLE 16

MINERAL ANALYSES OF CITRUS PACKING PLANT WASTES[a]

(Constituents in parts per million)

	Type of waste				
	Decco	Soda ash	Borax	Soda ash and hypochlorite	Soap and Red Star Crystals

% Sodium	34	96	99.7	97	95

a From "Progress Report on Possible Ground Water Pollution from Waste Water Produced from Citrus Packing Plants in Ventura County California", August, 1951[17].

b Approximately 400 ppm of this sodium is contained in organic compounds such as soaps of the fatty acids.

Waste discharges from citrus packing plants were investigated and reported upon by the Los Angeles Regional Water Pollution Control Board (No. 4) in August, 1951. The results of that investigation are reported in the "Progress Report on Possible Ground Water Pollution from Waste Water Produced from the Citrus Packing Plants in Ventura County".[17] The following information is extracted from that report.

In 1951, there were 28 citrus packing plants in operation in Ventura County. Two of these plants discharged their waste to cesspools, 14 to nearby stream channels, and seven to community sewer systems with ultimate disposal to pond or stream. Five plants discharged waste into sewers with ultimate discharge to the Pacific Ocean. It was estimated that roughly 8 tons of boron, 1.4 tons of chloride, and 12.75 tons of sodium were annually disposed to land by citrus packing plants.

The report prepared by the Regional Water Pollution Control Board recommended an investigation to be undertaken by the citrus industry to develop safe and permanent means for the disposal of waste water produced from packing plants in Ventura County on an industry-wide basis. As a result of this report, the industry formed a Water Pollution Committee of the Ventura County Citrus Packing Association to investigate ways and means of reducing or eliminating deleterious materials from the waste discharges. The cooperation of the packing plants in this effort to protect water quality is demonstrated by the fact that five of seven plants formerly using boron processes changed to cleaning agents containing little or no boron.

Waste discharge and disposal practices for each packing plant whose waste may have an effect on the quality of water is presented in Table 17 entitled "Significant Industrial Waste Disposals, Ventura County - June 1954". Locations of the discharges are delineated on Plate 12.

TABLE 17

SIGNIFICANT INDUSTRIAL WASTE DISPOSALS, VENTURA COUNTY - JUNE 1954

Map number	Location (S.B.B.&M.)	Industry or source of waste	Waste material	Quantity of waste disposed gal/min	Disposal practices	Remarks
			VENTURA RIVER DRAINAGE SYSTEM			
			Ojai Basin			
Citrus Processing		Ojai Orange Association	Waste water containing soda ash and hypochlorite	--	Discharged to Ojai sewer system	See effects of disposal from Ojai sewage treatment plant located in 4N/23W-12F
Miscellaneous		Culligan Soft Water Service	High chloride water from regeneration of water softeners	--	Discharged to City of Ojai sewer system	See effects of disposal from Ojai sewage treatment plant located in 4N/23W-12F. Discharge, 96 tons of salts per year.

Water Softener Regeneration Wastes. As has been stated, the waters of Ventura County are generally very hard. Total hardness concentrations nearly always exceed 200 ppm and values exceeding 600 ppm are not uncommon. Hardness in water utilized for domestic and industrial purposes requires excessive quantities of soap and causes scaling of boilers and plumbing fixtures. Excessive cost and inconvenience have resulted in increased use of ion exchange type water softeners.

There are two general types of ion exchangers, cation exchangers and anion exchangers. The cation exchangers may be subdivided into hydrogen cycle exchangers and sodium cycle exchangers, while anion exchangers may be divided into weakly basic exchangers and strongly basic exchangers. Of these exchangers only the sodium cycle softener is extensively utilized, the other softeners having only limited industrial application at the present time. The sodium cycle softener removes calcium and magnesium ions from solution and replaces them with sodium ions. When the capacity of the exchange medium (commonly called zeolite) has been reached, it is regenerated by permitting the material to come in contact with a highly concentrated sodium chloride solution.

In general, the two regeneration systems in common usage are the central regeneration system and the privately-owned system. In the former, a commercial agency rents water softeners to domestic and commercial establishments. The exchange medium is periodically replaced with the used material which has been regenerated at a centrally-located plant. Privately-owned softeners are normally regenerated by the owner. Wastes from the regeneration process include the backwash used to remove silts and fines from the exchange material, the regeneration solution, and rinse water used to remove the regeneration solution from the exchange medium.

Typical mineral analyses of waste from both centrally-regenerated and privately-owned softeners are given in Table 18, entitled "Mineral Analyses of Water Softener Regeneration Wastes". These data indicate that the regeneration solution and the predominate portion of the rinse wastes contain extremely high concentrations of sodium, chloride, and total dissolved solids. Backwash waste water, however, appears to be little impaired in quality.

a. Data from "Investigation of Waste Discharges from Water Softening Units Los Angeles Region", 1955[5].
b. Composite of two samples.
c. Composite of four samples.

Waste discharges from ion exchange type water softening units were investigated and reported upon to the Los Angeles Regional Water Pollution Control Board (No. 4), in 1955, by the former Division of Water Resources.(5) In this investigation, it was found that there are four central regeneration plants discharging wastes which could ultimately affect the quality of water supplies. Two plants, the Culligan Soft Water Service in Santa Paula and Ojai, discharge to the Santa Paula and Ojai sewage treatment plants. As previously stated, discharges from these sewage treatment plants percolate to economically important ground water bodies. The other two central regeneration plants dispose of wastes in areas where percolation to usable ground water does not appear probable.

Recent ordinances passed by the cities of Ojai and Santa Paula restrict the discharges of water softener wastes to the respective sewerage systems. These ordinances were drafted and adopted in order to reduce the mineral content in the effluents from each of the sewage treatment plants to meet the Regional Water Pollution Control Board requirements.

Pertinent data concerning central regeneration plant discharges in Ventura County are presented in Table 17 "Significant Industrial Waste Disposals, Ventura County". Regeneration wastes from privately-owned softeners, both domestic and industrial, are usually discharged to the sewage disposal system used for other wastes, either cesspool, septic tank, or a community sewerage system.

Estimates of the quantities of salt in regeneration wastes discharged annually to areas where less percolation to economically important ground water bodies is possible are presented in Table 19, entitled "Estimated Quantities of Water Softener Regeneration Waste Effectively Discharged

to Land in Ventura County". These estimates were based upon sales by salt companies, reports from central regeneration plants, and specifications for regeneration of softeners, combined with statistics obtained from census reports and previous surveys of water softener density.

TABLE 19

ESTIMATED QUANTITIES OF WATER SOFTENER REGENERATION WASTES EFFECTIVELY DISCHARGED TO LAND IN VENTURA COUNTY[a]

Stream system	Salt as NaCl used for regeneration, in tons per year: Central regeneration plants	Domestic units	Industrial units	Totals
Ventura River above Foster Park	96	70-155	20	186-271
Santa Clara River above Oxnard Plain Basin	108	195-440	134[b]	437-682
Calleguas Creek	0	60-135	40	100-175
TOTALS	204	325-730	194	723-1,128

a. From report "Investigation of Waste Discharge from Water Softener Units. Los Angeles Region, 1955"(5).
b. Includes four tons per year used by State institution.

Walnut Packing Plants. Walnut packing plants in Ventura County process approximately 10,000 tons of walnuts annually. Nuts received from the field are graded, cleaned, bleached, dried, and sacked prior to shipping. The agent used for cleaning and bleaching is a sodium hypochlorite solution containing 1.6 per cent, by weight, of available chlorine. Liquid waste from walnut packing plants consists of the spent cleaning and bleaching solution. Disposal of the liquid waste,

which is sodium chloride in character, is by discharge to seepage ponds, cesspools, streams, or sewers.

Waste disposal practices of walnut packing plants were investigated and reported upon by the Los Angeles Regional Water Pollution Control Board (No. 4) in January, 1953.[18] At the time of the survey, there were six walnut packing plants in operation in Ventura County, with ultimate discharge of waste to land areas subject to percolation. The quantity of waste and method of discharge of each plant is given in Table 17. Location of discharge points is shown on Plate 12. It was indicated that about 13.6 tons of sodium chloride per year is contained in the waste from walnut packing plants.

Refuse Disposal. One of the common means of disposal for solid, semi-solid, and liquid wastes is dumping in areas essentially unsuited for alternate development to dump sites. Wastes range from solid inert materials, such as earth and concrete, to noxious industrial liquid wastes containing high concentrations of dissolved salts, acids and caustics. Wastes include the combustible and noncombustible refuse and rubbish produced from households and commercial establishments. It is apparent that, if waters of the State are to be protected from pollution by such wastes, care must be taken in the selection of dump sites and in the proper operation of dumps.

Dump sites have been classified by the Department of Water Resources on the basis of the geology, hydrology, and topography. Based upon recommendations made by the former Division of Water Resources, in 1952, the Los Angeles Regional Water Pollution Control Board (No. 4), in August, 1953, adopted "Tentative Objectives for Prevention and Control of Water Pollution with Respect to Disposal of Wastes on Land in Ventura County within Los Angeles Water Pollution Control Region". The tentative objectives classified

dump sites as follows:

"Class I - DISPOSAL SITES

Sites located on nonwater-bearing rocks or underlain by isolated bodies of unusable ground water, which are protected from surface runoff and where surface drainage can be restricted to the site or discharged to a suitable wasteway, and where safe limitations exist with respect to the potential radius of percolation.

CLASS II - DISPOSAL SITES

Sites underlain by usable, confined, or free ground water when the minimum elevation of the dump can be maintained above anticipated high ground water elevation, and which are protected from surface runoff and where surface drainage can be restricted to the site or discharged to a suitable wasteway.

CLASS III - DISPOSAL SITES

Sites so located as to afford little or no protection to usable waters of the State."

The Regional Water Pollution Control Board designated typical wastes which could be disposed of in each class of disposal site. In general, all types of waste may be disposed of in Class I sites. Class II sites may receive ordinary household refuse and rubbish and all materials approved for disposal in Class III sites. Garbage may also be accepted at Class II sites, provided such disposal does not conflict with local public health laws. The only materials suitable for disposal in Class III sites are innocuous, relatively inert, wastes such as dirt, concrete, and plaster.

Dump sites in Ventura County were investigated by the Los Angeles Regional Water Pollution Control Board (No. 4), in September, 1952. It was found that nine dumps in the county are either owned or operated by the County of Ventura. These include the Ojai, Saticoy,

[illegible] dumps. In addition, [illegible] sites were surveyed by the State [illegible], Oxnard, and Ventura. Ten private dump sites were found in the survey.

[illegible] mapping the classification of these sites [illegible] Table 17, and [illegible] Plate 12. [illegible] dumps receive [illegible] ing the reduction of the volume of waste material. Disposal of garbage was practiced only at the City of Oxnard dump site. A county ordinance prohibits the disposal of garbage to county owned or operated dumps.

Miscellaneous Waste Discharges. This category includes a relatively small number of discharges, such as hog farm wastes, metal cleaning wastes, fruit and vegetable processing wastes, and ammonia manufacturing wastes. Information concerning these discharges is presented in Table 17, and locations of points of disposal are delineated on Plate 12.

Sea-Water Intrusion

The quality of the water contained in a coastal ground water basin may be seriously affected by the intrusion and admixture of sea water. Intrusion may take place when water-bearing deposits along the seaward or bayward margins of ground water basins are in direct contact with the ocean or bay floor at the shore line, or extend beneath the ocean floor.

Intrusion can occur only when the pressure head of sea water

exceeds that of the fresh ground water, a condition usually resulting when ground water levels are lowered to or below sea level by excessive pumping of wells. When the hydraulic gradient within a ground water basin slopes seaward, ground water movement is toward the ocean; conversely, with a landward slope, inland movement of sea water occurs. The slope and direction of the hydraulic gradient is established by measurements of the depth to water in observation wells.

It has been shown that mineral analyses of certain of the wells in the Oxnard Plain Basin in the vicinity of Port Hueneme evidenced higher concentrations of chloride and dissolved solids than found in other waters of the Oxnard aquifer. Wells affected in summer, 1957, included Nos. 1N/22W-19H1, 20E1, 20N1, 20R1, 21L1, 21L2, 28D1, 29A2, and 29C1. Complete mineral analyses of samples collected from these wells are presented in Appendix B. Partial mineral analyses are presented in Appendix C.

A thorough study of this portion of the aquifer reduced the probable sources of chloride degradation in the ground water to one or more of the following:

1. Sea-water intrusion through the Oxnard aquifer.
2. Percolation or leakage through poorly constructed wells, defective casings, or abandoned wells, by
    a. Irrigation return water and other poor quality waters from the semiperched ground water body.
    b. Sea water which has intruded into the semiperched ground water body.

To differentiate between sea water and semiperched water, Plate 13, entitled "Mineral Character of Ground Water in the Vicinity of Port Hueneme and Point Mugu", has been prepared. Anion constituents only

were used on this chart, since cation constituents are subject to character changing influences, such as cation exchange. This plate shows the anion constituents, expressed in per cent, in the degraded water and in the two apparent sources of degradation. Anion constituents in ground water from these wells prior to degradation are also plotted on this plate. The indicated source of degradation of ground water pumped from wells in the vicinity of Port Hueneme and Point Mugu was sea water. The character of the anion constituents in the degraded water plots almost in direct line between water samples representative of the native water and sea water. There is no apparent influence of the semiperched waters.

In an effort to distinguish between the methods by which sea water is enabled to enter the aquifer, consideration was given to the hydrologic and geologic conditions existing in the area of intrusion. As described in Chapter II, the Oxnard aquifer appears to outcrop in the submarine canyon near Port Hueneme. Furthermore, the semiperched zone extends under the coastal sand dunes to the ocean. Thus, from the geologic standpoint, sea water may enter either of the water-bearing zones. Before sea-water intrusion can occur, however, the hydraulic head of sea water must be greater than that prevailing in the aquifer.

Information obtained from the studies of Division of Soils of the University of California at Los Angeles is of significance in analyzing the data available regarding the semiperched water body. It is indicated that the elevation of the semiperched water table throughout the Oxnard Plain is above sea level, with the hydraulic gradient sloping toward the ocean, thus precluding sea-water intrusion in this zone.

A trough of piezometric water pressure levels depressed below

sea level has existed continuously in the Oxnard aquifer since 1949, a condition conducive to sea-water intrusion. The correlation between below sea level piezometric elevations in the Oxnard aquifer and saline intrusion, is indicated by Plate 14, entitled "Chloride Ion Increase - Well 1N/22W-29A2". On this plate, the hydrograph of well 1N/22W-20R1 is plotted, together with the average weekly chloride concentration in well 1N/22W-29A2, both perforated in the Oxnard aquifer.

Inspection of this plate will show that during the period when the water level in well 20R1 was lowest, the rate of increase in chloride concentration in the ground water was greatest, once degradation became initiated. As an example, during the period from September 1,to December 13, 1951, water levels in well 20R1 slowly rose from about 14 feet to about two feet below sea level, and the increase in chloride concentration in well 29A2 averaged 3.9 parts per million per day. In the subsequent period, December 13, 1951, to March 19, 1952, water levels were slightly above sea level and the increase in chloride concentration was reduced to about 1.5 parts per million per day.

Although it appears contradictory that the chloride concentration should have increased while the water level in the key well was slightly above sea level, this condition exists because the top of the Oxnard aquifer is between 80 and 120 feet below sea level. At this depth, because of the difference in density, the elevation of fresh water must be more than two feet higher than sea level in order to effect a balanced condition. Since there exists a seaward hydraulic slope in the semiperched ground water body, it appears from the correlation between water levels in the Oxnard aquifer and the increase in chloride ion

concentration, that sea water is entering directly into the Oxnard aquifer through ocean floor outcrops.

As of December, 1954, about 930 acres in the Oxnard Plain were underlain by waters degraded to 100 ppm chloride by sea water. By the summer of 1957, this area had increased to 1,550 acres. The extent of saline intrusion in the Oxnard aquifer is shown on Plate 15, entitled "Areal Extent of Sea-Water Intrusion, Vicinity of Port Hueneme". The advance of sea-water intrusion into the Oxnard aquifer, as estimated by the detection of 100 parts per million chloride in wells, has averaged approximately 1,200 feet per year in a northerly direction, and 700 feet per year in an easterly direction since 1951.

Prevention of sea-water intrusion in this aquifer may be accomplished by reversal of the hydraulic gradient, either by decreased pumping or by increased recharge, or both.

Salt Balance in Ground Water Basins

The use of ground water storage capacity in conserving and regulating both local and imported water supplies, particularly those supplies intended to be used consumptively by irrigated agriculture, requires a consideration of the salt balance involved in the use and re-use of the available supplies. Salt balance refers to that desirable condition wherein the amount of soluble salts entering a basin is balanced by the amount of salt leaving the basin -- either by natural disposal, sewage outflow, or by pumping for export, waste disposal, or drainage.

As man develops an area he disturbs the existing salt balance by changing the natural regimen of ground water flow and by adding salts in wastes permitted to percolate. If the change in the natural regimen results in a

condition of adverse salt balance, the total tons of dissolved solids in the ground water will increase. This increase in total salt content will, in time, be compensated by an increase in the quantity of salts leaving a basin through pumping or natural drainage, and the basin will eventually reach equilibrium, although at a greater average salt content.

The problem of salt balance exists in most of the developed ground water basins of California, and must be considered if the basins are to retain their important place in conservation and utilization of the water in the State. The solution involves induced drainage of water from the basins in amounts sufficient to maintain satisfactory mineral quality therein. The amount of water so drained away will constitute a demand on the developed water supply.

Practically all natural waters contain mineral salts of calcium, magnesium, sodium, and potassium in varying amounts, present in the waters in the form of carbonates, sulfates, nitrates, and chlorides. After application of water on the land, that part which is not consumptively used and which does not drain off on the surface, will percolate to the main body of ground water in free ground water basins. Minor amounts of salt compounds will be utilized in plant growth and conversely, percolating water will dissolve or absorb other salt compounds in passing through the soil between the surface and the water table.

Under natural conditions most ground water basins tend to fill with water and to overflow in the lower portions, thereby flushing out soluble salts contained in water originating on the tributary watershed and overlying lands. When aquifers in the basin are tapped by wells, the pumping draft lowers ground water levels to such an extent that in many

cases the natural flushing of the basin ceases. Since the pumped water is largely used on overlying lands, soluble salts accumulate within the basin and tend to degrade the quality of the ground water in storage. If the situation is such that no discharge of water from the area, either surface or subsurface, occurs, the concentration of salt compounds in the remaining water will become so great in the course of time as to inhibit its use as a source of water supply. This is particularly true in the case of irrigation supplies, as crops generally have rather low tolerance for dissolved salts.

In general, a favorable salt balance can be established in the given area by deliberately inducing outflow of water from the area in such amount that the total quantity of mineral salt exported is equal or greater than the quantity imported. Under these conditions, the long time mean quantity of salts is maintained relatively constant. The maintenance of such balance, or the removal of a total amount of salt from an area exceeding the salt input to the area (termed "favorable salt balance") does not necessarily imply lack of damage to the lands and crops. It is also important to determine whether a favorable salt balance is being maintained in the root zone of the irrigated crops, as accumulations of salt compounds in that zone will prevent the successful culture of many irrigated crops.

In previous portions of this chapter various sources which may contribute concentrated salt solutions to surface and ground waters have been enumerated. The cumulative effect of these contributions is dependent upon the relative concentrations in the waters forming the mixture. The usual result is an increase in the concentration of the various mineral constituents in the receiving waters. When discharged into a surface stream, salts are rapidly carried away. However, since ground water moves slowly, contributed

salts are not so rapidly discharged or diluted. It is also possible for salts to be contributed to ground water at a rate greater than the capability of the aquifer to transmit, dilute, and discharge them.

Safe ground water yield is defined as the maximum rate of extraction of water from a ground water basin which, if continued over an indefinitely long period of time, would result in maintenance of certain desirable fixed conditions. One of these conditions is, that water levels are not so lowered as to cause permanent accumulation and concentration of salts or pollutants, whether from surface percolation of wastes or from subsurface intrusion of water of undesirable quality. Overdraft is defined as a condition of development under which extractions from the ground water reservoir produce an adverse effect or series of effects. If development of a basin occurred to the extent that an adverse salt balance results in the accumulation and concentration of salts and pollutants, an overdraft condition would exist. Thus, overdraft for any particular ground water basin must be defined in terms of the conditions existing for that basin at a specific time.

In Chapter V, data were presented indicating that ground waters in many of the basins of Ventura County were of marginal quality for many of the prevailing beneficial uses. Furthermore, in basins where sufficient antecedent data were available to compare with recent analyses, it is indicated that there has been, during recent periods, a measurable deterioration in quality. It would appear that an adverse salt balance may exist in these basins.

Identification of the source of such adverse balance, the quantity and rate of accretion, the quantitative expression of foreseeable

results, and the formulation of recommendations for correcting or alleviating the effect of adverse salt balance, will require the maintenance of detailed records of mineral quality of water for a considerable period of time.

Santa Felicia Dam on Piru Creek was completed in 1955, and Casitas Dam now under construction is scheduled to begin storing water during the winter season of 1958-59. Numerous other plans for the development of water supplies in Ventura County have been advanced. These works, when constructed, will alter the natural regimen of surface streams and ground water basins and may affect the maintenance of salt balance.

Summary

The surface and ground waters of Ventura County are, in the course of their movement to the ocean, subject to degradation from natural sources and to pollution from sewage and industrial wastes. Furthermore, development of water supplies has altered the regimen of many of the basins and in some instances resulted in deterioration of water quality.

The surface waters of Ventura County are subject to degradation by highly mineralized waters flowing from hot springs and by poor quality effluent ground water. Runoff from rainfall on certain of the geologic deposits in Ventura County contains high concentrations of boron. This has affected the quality of certain streams, with particular reference to low flows, to the point of becoming marginal for irrigation use. Natural degradation of ground water is accomplished primarily through deep percolation of poor quality surface waters and by the subsurface movement of highly saline waters from marine deposits of Tertiary age.

As the result of man's development of the surface and ground waters

of Ventura County, deterioration and/or pollution has occurred. A large portion of Ventura County has been developed for irrigated agriculture. Irrigation return water with high mineral concentrations has commingled with native ground waters and resulted in increased salt concentrations. Numerous industries have been developed in Ventura County. Certain of these industries discharge wastes as a result of their processes. These can, upon commingling with ground waters, result in excessive degradation. Included among these wastes are oil industry wastes; fruit, nut, and vegetable packing wastes; and water softener wastes. Commercial and domestic rubbish and refuse are disposed to dump sites, together with certain of the more noxious industrial wastes. If these wastes are disposed of in an improper manner, salts may be leached, resulting in a degrading effect on ground waters. Waste discharges from many of these sources have been investigated by the Department of Water Resources for the Los Angeles Regional Water Pollution Control Board (No. 4). In many instances measures have been taken to correct improper discharge practices.

Continued pumping of large quantities of water, in excess of safe yield, from the Oxnard aquifer of the Oxnard Plain Basin has resulted in the depression of piezometric levels below sea level in portions of the basin and the intrusion of sea water into the aquifer. As of summer, 1957, the area underlain by sea water was about 1,550 acres. It was estimated that during the period 1951 to 1957, in the vicinity of Port Hueneme, the saline front advanced at the rate of about 1,200 feet per year in a northerly direction and about 700 feet per year in an easterly direction.

Improperly constructed and abandoned wells may be a factor in transmission of pollution or degradation to usable ground water. Such

wells may serve as a conduit for poor quality surface or drainage waters, leaching effluent from cesspools and septic tanks, surface wastes, or poor quality perched or connate waters, permitting contacts with, or intrusion into, aquifers utilized as a source of water supply.

The integrated effect of all sources of deterioration and pollution of ground waters is indicated by the salt balance prevailing in a ground water basin. Analyses made during the past 20 years indicate considerable deterioration in water quality in the Fillmore and Santa Paula Basins. If deterioration should continue over a protracted period, it could result in the loss of the ground water resources for beneficial purposes.

Future studies of salt balance problems in Ventura County, and the formulation of policies and recommendations for the alleviation of adverse salt balance conditions will be facilitated through the use of data collected since 1952 by the Department of Water Resources in the State-wide Surface and Ground Water Sampling Programs.

CHAPTER VII. RECLAMATION OF WATER FROM SEWAGE

Plant effluents are generally available for re-use unless discharged to saline water or lost through evapo-transpiration. In Ventura County, incidental reclamation or the recovery of waste waters for beneficial use results from the disposal of effluents from the City of Santa Paula, Camarillo State Hospital, and Camarillo Sanitary District through their use for irrigation during a portion of the year. The recovery of waste waters which have lost their identity through mixing with natural stream flow or ground water in the process of final disposal is termed involuntary reclamation. Examples in Ventura County are the discharges to stream channels from the City of Ojai and discharges from the Saticoy Sanitary District and the City of Fillmore to percolation lagoons. In addition, effluent from the City of Santa Paula is discharged to the Santa Clara River when not used for irrigation.

The above discharges constitute the principal inland disposals of domestic sewage in Ventura County. With the exception of the discharge from Camarillo State Hospital to Calleguas Creek during intervals when the effluent is not being used for irrigation, all of these effluents are susceptible to involuntary or incidental reclamation. The flow from these sewage treatment plants, serving a combined population of some 28,000 persons, was approximately 2.5 million gallons per day, or about 2,800 acre-feet during the fiscal year 1956-57.

During 1957, the Montalvo Sanitary District discharged about 170 acre-feet to percolation ponds. Effluent from these ponds seeps to an apparently unused shallow ground water zone that is essentially isolated from the deeper productive zones.

Planned reclamation of water from sewage refers to the salvage of waste water which would otherwise be lost. During fiscal year 1956-57, 7.5 million gallons a day, equivalent to 8,400 acre-feet per year, was discharged to the Pacific Ocean by the Cities of Ventura and Oxnard, the Port Hueneme Sanitary District, and the Port Hueneme and Point Mugu Naval Reservations. The discharges from the Cities of Ventura and Oxnard constitute about 80 per cent of this quantity and consequently appear to offer the best opportunity for planned reclamation.

In-plant reclamation of waste water by industry is frequently overlooked, although it is a phase of reclamation which can result in substantial reduction in water consumption and subsequent waste discharge. Re-use frequently requires partial purification of the water and this treatment may not be economically justifiable solely on the basis of water reclamation. Additional benefits which may accrue from such practices include:

1. Reduction of the hydraulic load on the waste treatment plant.
2. Enhancement of the possibility of by-product recovery, due to concentration.
3. Salvage of heat and chemicals contained in the waste water.
4. Better public relations in communities suffering from water shortages.
5. Better public relations in communities with waste disposal problems.

Recycling of white water from a paper-making machine, for example, results in savings of water and heat, and effects reclamation of useful chemicals and materials.

Prior Studies of Water Reclamation in Ventura County

The City of Ventura and Shell Oil Company with its subsidiary, Shell Chemical Corporation, entered into an agreement whereby the company would study the feasibility of reclaiming the effluent from the City's sewage treatment plant for industrial use. Pilot plant studies were initiated to ascertain the feasibility of utilizing reclaimed water, primarily for cooling tower make-up and boiler feed, in an ammonia plant and for other industrial purposes in the Ventura Avenue Oil Field. However, as yet no positive action has been taken to further the possibility of water reclamation.

Utilization of wastes discharged to the ocean by the City of Oxnard was the subject of a report prepared by V. M. Freeman, Engineer, Santa Clara Water Conservation District.[13] In this report, it was proposed to pump effluents from the Oxnard secondary and Port Hueneme primary treatment plants to oxidation lagoons for polishing treatment. After a 10-day retention period the lagoon effluent would be pumped a distance of 42,500 feet to a proposed Ditch Road Spreading Ground or as an alternate plan 57,000 feet to the Saticoy Spreading Ground. On the basis of 1949 prices, it was estimated that the cost of water reclaimed by this method would range from $17 to $21 and $15 to $19 per acre-foot, respectively. As of this date, no action has been taken on the findings of this report.

Plans for Reclamation of Water from City of Oxnard Sewage Treatment Plant Effluent

The possible markets for water reclaimed from City of Oxnard sewage include direct industrial use, recharge of ground water basins, supply for injection wells to prevent sea-water intrusion, and direct irrigation use. The successful use of reclaimed water for each of the above purposes is contingent upon the quality of the sewage. This section discusses the quality of the effluent from the City of Oxnard sewage treatment plant, the possibilities for industrial use, direct irrigation use, recharge of ground water basins, and supply for injection wells to prevent sea-water intrusion.

Quality of Effluent from the City of Oxnard Sewage Treatment Plant

The mineral quality of effluent from the Oxnard sewage treatment plant is poor. Available mineral analyses, which are presented in Appendix D, indicate the following ranges and averages in mineral quality characteristics: total dissolved solids, 1,351 to 2,120, averaging 1,583 parts per million; effective salinity, 13.4 to 25.3, averaging 16.2 epm; boron, 0.6 to 1.5, averaging 1.0 ppm; and chloride, 174 to 500, averaging 231 ppm. The character of the effluent is generally sodium-calcium sulfate with total hardness ranging from 572 to 688, averaging 629 ppm.

Sanitary analyses of the effluent from the Oxnard sewage treatment plant are presented in Appendix D. A new activated-sludge type treatment plant was put into operation on June 23, 1956. The old sewage treatment plant, now abandoned, is a trickling-filter type plant. Since the new plant has been in operation, the biochemical oxygen demand (B. O. D.) of the effluent has ranged

from 30 to 77, averaging 58 ppm. The analyses also show the effluent from the new plant to have a most probable number of coliform bacteria (MPN) ranging from 24,000 to 240,000, with a median value of 70,000.

The poor quality of water supplied to the area sewered by the City of Oxnard is a major contributing factor to the poor mineral quality of the sewage. However, there is also an abnormally large mineral increment, particularly in chlorides, when compared to normal ranges as presented in a report published by the California State Water Pollution Control Board.(9) This relationship is summarized below:

Item	Effective salinity, epm	Total dissolved solids, ppm	Chloride, ppm	Boron, ppm
Quality of supply water[a]	8.83	1,165	54	0.6
Quality of sewage[b]	16.75	1,516	235	0.9
Mineral increment	7.92	351	181	0.3
Normal increase in mineral content (9)	---	100-300	20-50	0.1-0.4

a. Average analyses of water from four wells collected May 8, 1958. These wells constituted the source of supply water during the month. The analyses were weighted in proportion to the approximate production from each well.

b. Sixteen-hour composite sample collected on May 14, 1958.

The principal causes for this abnormally large mineral increase are the infiltration of highly mineralized shallow ground waters into the sewers and the discharge of highly mineralized wastes from industries and home water softeners. The diversion of highly mineralized waste discharges from the domestic sewer to the industrial waste sewer would improve the mineral quality of the sewage treatment plant effluent.

Industrial Use

As indicated by the above water quality discussion, water reclaimed from the City of Oxnard sewage could be utilized by industry. However, the effluent from the treatment plant would probably have to be given additional sanitary treatment before being acceptable for industrial use. For most industrial uses, waters with relatively low B.O.D., turbidity, and color are required.

At the present time, there is no large-scale potential industrial market for water reclaimed from sewage known to exist in the Oxnard area. A pulp and paper manufacturing plant, located close to the City of Oxnard sewage treatment plant, has considerable potential as an industrial market for reclaimed water. However, the present water requirement for this plant is only about 800-1100 acre-feet per year. Also, some additional treatment of the effluent would be necessary to render it suitable for some of the major uses in the plant. No complete cost estimate, which would include distribution costs, has been made for industrial use of water reclaimed from the City of Oxnard sewage.

Recharge of Ground Water Basins

As noted in a previous section of this chapter, detailed engineering studies have been made of the use of sewage effluents for recharge of ground water basins of the Oxnard area.[13] The recent completion of Santa Felicia Dam, however, making additional quantities of natural surface waters available for spreading, has detracted from the desirability of spreading reclaimed water.

In addition, the recycling of sewage by means of ground water recharge appears undesirable because of the prevailing water quality problems in the ground water basins of the area.

Repulsion of Sea-Water Intrusion

The California State Water Pollution Control Board sponsored a 44-month field study of direct recharge into underground formations. The work was performed by the University of California at its engineering field station at Richmond. The results were published as California State Water Pollution Control Board Publication No. 11, "Report on the Investigation of Travel of Pollution", 1954.

Fresh water was recharged into a pressure aquifer for which the permeability was about 1,900 gallons per square foot per day, over long periods of time with no operational difficulties. The addition of sewage plant effluents at the same rate, however, caused clogging of the well at a rate which was proportional to the amount of solids injected. Under permissible well head pressure buildup, a liquid waste equivalent to the final effluent from secondary sewage treatment could be injected for about eight or nine days. After that time, redevelopment of the injection well was necessary. Chlorine injection, followed by a half day of contact and three or four hours of pumping at a rate equal to twice the injection rate, re-established the ability of the aquifer to receive injected water.

As a result of research reported in the California State Water Pollution Control Board Publication No. 11, it was concluded that the reclamation of sewage effluent by direct recharge into sand aquifers is not limited by public health concern over bacterial contamination.

In regard to public health consideration, Section 4458 of the California State Health and Safety Code specifically prohibits the construction, maintenance, or use of any sewer well extending to or into a subterranean water-bearing stratum that is used or intended to be used as, or is suitable for, a source of water supply for domestic purposes. The same section defines a sewer well as any hole dug or drilled into the ground, used or intended to be used for the disposal of sewage. The legal use of sewage treatment plant effluent in injection wells to establish a barrier to sea-water intrusion in producing aquifers may require revision of the California State Health and Safety Code.

The use of effluent in injection wells to establish a barrier to sea-water intrusion in the producing aquifer of the Oxnard area would result in the re-use of a portion of such water for beneficial purposes. Because of the water quality problems of the area, and since injected water would eventually be subject to domestic use, it would be desirable to use waters with dissolved mineral content conforming to the United States Public Health Service drinking water standards.

Direct Irrigation Use

Water reclaimed from the City of Oxnard sewage would be generally unsuitable for continued irrigation use because of its poor mineral quality. If, however, such water were combined with waters of the Oxnard aquifer in the ratio of about two parts of ground water to one part reclaimed water, the resulting mixture would have a total dissolved solids concentration of about 1,100 ppm and an effective salinity of about 10 epm. This mixture would be of a quality that could be utilized for irrigation purposes under conditions which exist in the tile-drained areas of the Oxnard plain.

In addition to meeting mineral quality requirements, waters reclaimed for irrigation use must conform with certain sanitary standards which are set forth in a Special Bulletin No. 59 of the California State Department of Public Health entitled, "Regulations for Use of Sewage for Irrigating Crops", May, 1933. Briefly, these standards provide that no raw or untreated sewage shall be used for irrigating crops; partially treated effluent may be used on fodder crops, field crops, and some orchard crops; well oxidized and thoroughly disinfected effluents may be used without restriction if bacterial standards approximating the United States Public Health Service drinking water standards are continually met, and no plumbing cross connections are permitted with any domestic water system.

On the basis of data presented in this chapter, it appears undesirable to use water reclaimed from the City of Oxnard sewage for recharge of ground water basins, supply for injection wells to prevent seawater intrusion, or direct irrigation. While reclaimed water could be diluted with ground water and then used for irrigation, the mechanics of such a procedure may be complex and may necessitate duplication of facilities. In addition to the foregoing, it seems probable that there will be an aesthetic reaction against using water reclaimed from sewage for direct irrigation.

The effluent from the City of Oxnard sewage treatment plant is of suitable mineral quality for certain industrial uses. Presently, however, only a small potential industrial market for water reclaimed from sewage exists in the Oxnard area. Therefore, an additional industrial

need should be manifested before further consideration is given to any plan to reclaim water from the City of Oxnard sewage treatment plant effluent.

CHAPTER VIII. WATER QUALITY ASPECTS OF WATER RESOURCES DEVELOPMENT

As a result of the comprehensive investigation which culminated in the preparation of State Water Resources Board Bulletin No. 12, entitled "Ventura County Investigation", it was concluded that current water resource problems in Ventura County include perennial and progressive lowering of ground water levels, overdraft on ground water supplies, sea-water intrusion into pumped aquifers and degradation of ground water quality. Recently completed studies of water requirements indicate that the supplemental water requirements will be about 85,000 acre-feet per year in 1960 and 236,000 acre-feet in the year 2020.

The investigation resulted in further conclusions to the effect that local supplemental water could be made available by conservation of runoff which presently wastes to the ocean from the Ventura and Santa Clara River watersheds, by construction of surface storage reservoirs and further development of ground water storage. Mean seasonal runoff to the ocean from the Ventura and Santa Clara River watersheds averaged about 230,000 acre-feet per season during the period 1936-37 to 1950-51. It is therefore apparent that even with complete regulation of runoff from these watersheds, additional supplemental water would have to be imported to meet ultimate requirements. Possible sources of such water include the Colorado River, through facilities of the Metropolitan Water District of Southern California, and waters from northern California, through facilities of the authorized Feather River Project.

As previously stated, alteration of the natural regimen of flow in any hydrologic system which includes both surface streams and ground

water basins will probably result in a change in quality of water. In the following paragraphs, there is presented a brief review of projects recently completed or under construction together with estimates of the effect of such developments on the quality of waters.

Development of Local Water Supplies

Ventura River Drainage System

Development of the Ventura River drainage system is centered around Casitas Dam and reservoir, which is now under construction by the United States Department of Interior, Bureau of Reclamation. This dam is on Coyote Creek at a point about two miles upstream of the confluence with the Ventura River. The reservoir will have a capacity of 250,000 acre-feet and will permit conservation of flood waters from Coyote Creek. In addition, the reservoir will store waters diverted from Ventura River.

In operation of the project, water will be pumped to the Ojai Valley and Upper Ventura River Service areas. Since the stored flood waters are of better quality than present ground waters of Ojai Valley, the effect of the project would be to improve ground water quality in Ojai Valley.

The new water made available by the Casitas Project will be derived from flood flows that presently waste to the ocean. As in most southern California streams, the quality of water in Coyote Creek and Ventura River is better at time of flood runoff than normal low flow or summer runoff. The conservation of flood runoff will probably result in improvement in the quality of water in the Ventura River at Foster Park.

Santa Clara River Drainage System

Santa Felicia Dam, on Piru Creek with a reservoir storage capacity of 100,000 acre-feet, was completed in 1955. The present plans of the United Water Conservation District are to release water from the dam to the natural stream channel, with subsequent diversion from Santa Clara River for percolation in spreading grounds or delivery to Oxnard Plain Basin via conduits.

Santa Felicia Dam will impound a major portion of the discharge from Piru Creek. Future flows in Piru Creek will consist of runoff originating from the drainage area below the dam, reservoir releases to the natural channel, and spill when the reservoir is full. The over-all quality of water in Piru Creek is considerably better than that found in the Santa Clara River above the confluence of the two streams.

Since waters to be impounded behind Santa Felicia Dam are essentially flood runoff of good quality, their net effect on the waters of the Santa Clara River system should be one of quality improvement.

Effect of Importation of Supplemental Water on Water Quality

Prior investigations resulted in the conclusion that the water resources of Ventura County are insufficient to meet estimated ultimate requirements. Importation of supplemental water supplies from either the Colorado River or Northern California is presently being given serious consideration. These two possible sources were studied to determine the effect of such importation on quality of waters in the county.

The Colorado River Aqueduct

Local interests have considered annexation of portions of Ventura County to the Metropolitan Water District for the purpose of obtaining supplemental water. On the assumption that the area included in the Calleguas Creek system would probably be the first to receive imported supplies, the relationship between the quality of Colorado River water and that in the various aquifers is indicated in Table 20.

Data given in the table represent an analysis of untreated Colorado River water and the maximum and minimum values for the individual constituents in water derived from the alluvium and other aquifers. In general, the value of each constituent in untreated Colorado River water lies between the minimum and the maximum values for the same constituent in the ground waters found in the Calleguas Creek system. This is not true, however, in the Tierra Rejada Basin, where certain of the maximum values are below the values for the same constituent in untreated Colorado River water. Since the quality of Colorado River water is, in general, comparable to that presently applied in the ground water basins of the Calleguas Creek system, quality of the return irrigation water would not be significantly different from that which presently returns to the ground water by deep percolation.

No studies were made to determine the effect of importing Colorado River water into other portions of Ventura County. The mineral character of untreated Colorado River water is similar to most waters found in Ventura County. Therefore, the utilization of untreated Colorado River water in Ventura County will not create any additional difficulties or problems of base exchange in the soils.

TABLE 20

COMPARISON OF UNTREATED COLORADO RIVER WATER AND MAXIMUM AND MINIMUM VALUES OF CONSTITUENTS IN GROUND WATERS IN CALLEGUAS CREEK DRAINAGE SYSTEM

Water-bearing formation		EC x 10^6 at 25°C	pH	Mineral constituents in parts per million										Total dissolved solids ppm	Effective salinity epm	Per Cent Na

The use of treated Colorado River water in Ventura County might create problems of base exchange in soils as the softened water has a high per cent sodium. Agricultural use of this water on certain soils could result in reduction of soil workability and crop production. Its use for ground water recharge might cause reduction in percolation rates in spreading grounds or leaching areas. However, treated water would probably have limited agricultural use due to economic considerations and it is believed that these problems would have a minimal occurrence.

San Joaquin Valley - Southern California Aqueduct

As stated in Chapter V, "Water Quality in Ventura County," the water to be delivered to southern California via the aqueduct will be calcium bicarbonate in character. The mean annual values of total dissolved solids will be less than 200 ppm, chlorides less than 40 ppm and total hardness less than 150 ppm. No water quality problems are anticipated if northern California water is imported as a supplemental supply for Ventura County. Because of its low mineral content, water from this source would tend to reduce the average concentration and salt content in the ground water basins of the County.

CHAPTER IX. CONCLUSIONS AND RECOMMENDATIONS

The results of this investigation of the water quality and water quality problems in Ventura County are summarized in the conclusions and recommendations presented in this chapter.

Conclusions

1. The principal sources of water supply presently available to Ventura County are direct precipitation on the valley floors and runoff from tributary drainage areas. Historically, the major regulation of surface runoff has been accomplished through percolation to ground water storage.

2. The principal water-bearing formations of Ventura County are the alluvial deposits covering the valley floors and aquifers of the San Pedro and Santa Barbara formations of Pleistocene Age. However, fractured Miocene volcanic rocks are important sources of water in Santa Rosa and Tierra Rejada Basins.

3. Beneficial uses of water in Ventura County include domestic and municipal, irrigation, industrial, recreation, and propagation of fish and wildlife. Surface and ground waters also serve as a means for the disposal of wastes.

4. In general the surface waters of Ventura County are suitable for nearly all beneficial uses during periods of high flow. However, during periods of low flow, waters from Canada Larga, Arroyo Simi, Hopper and Tapo Creeks, and Santa Clara River at Blue Cut contain sufficient concentrations of dissolved salts to render them marginal or unsuitable for many uses.

Matilija, Sespe and Piru Creeks contain high concentrations of boron during low flow.

5. Waters of good mineral quality are generally produced from the Miocene volcanics in Conejo, Tierra Rejada, and Santa Rosa Basins. In Ojai and Upper Ojai Basins ground waters produced from Recent and Plesitocene deposits are of good mineral quality. In other basins the preponderance of ground water produced from alluvial deposits ranges from suitable to marginal or unsatisfactory for prevailing beneficial uses. Ground waters of such poor quality that they are essentially unusable include the waters in the Recent alluvial deposits of the Lower Ventura River Basin and the semiperched ground waters found in the Oxnard Plain Basin. In addition, there are localized areas within the various ground water basins of the County where the ground water is of very poor quality. Included among these are the semiperched zone near the west end of Simi Basin, the area south of the Oak Ridge fault in Fillmore Basin, and the extreme easterly portion of Upper Ojai Basin.

6. In areas where sufficient antecedent data are available it is indicated that the quality of ground water has deteriorated measurably during the past 20 years. Included among these areas are Ojai, Fillmore, Santa Paula, Piru, and Oxnard Forebay Basins, and the Oxnard aquifer of the Oxnard Plain Basin. There are insufficient data available to permit determination of quality trends in basins of the Calleguas Creek drainage system.

7. Surface waters of Ventura County are subject to degradation by highly mineralized waters from hot springs and by effluent ground water of poor quality. Runoff from certain areas tributary to Matilija, Sespe, and Piru Creeks contains high concentrations of boron and other salts dissolved from geologic deposits with which it comes in contact.

8. The principal ground water bodies have been degraded by deep penetration of surface waters of poor quality; by sea water intrusion; by subsurface inflow from semipermeable formations containing waters of poor quality; and by ingress of poor quality semiperched waters by slow percolation through tight materials underlying the water body, movement around discontinuous clay lenses which may serve to support the zone, and interconnection of aquifers through broken casings, improperly constructed or abandoned wells or through wells with gravel envelopes.

9. Basins where proper well construction and abandonment is considered important include Santa Paula, Oxnard Plain, Pleasant Valley, Mound, Simi, and East and West Los Posas Basins.

10. Ground waters are subject to deterioration by the disposal of sewage to cesspools, septic tanks, and sewage treatment plants with land disposal of final effluent. With respect to sewage treatment plants with land disposal of effluent, available data do not indicate any deterioration of ground water from discharges of the Saticoy Sanitary District, and the Camarillo State Hospital. However, there is evidence to indicate localized deterioration of ground water as the result of discharges from the Santa Paula and Ojai sewage treatment plants.

11. The principal industrial wastes which may impair or pollute surface and ground waters in Ventura County include discharges to land by the oil industry, citrus packing plants, and walnut packing plants. Water softener regeneration wastes, which are not restricted to industrial sources, and disposal to dump sites may also be sources of impairment. Waste discharges from many of these sources have been the subject of investigations by the Department of Water Resources and the Los Angeles Regional Water Pollution Control Board (No. 4). In many instances, measures have

been taken to correct those discharge practices which would otherwise have an unfavorable effect on the quality of water supplies in Ventura County.

12. Excessive pumping from the Oxnard aquifer of the Oxnard Plain Basin has resulted in the depression of piezometric levels below sea level in portions of the basin and the intrusion of sea water into the aquifer at Point Mugu and Port Hueneme. In the summer of 1957, the area underlain by sea water amounted to about 1550 acres. The rate of saline encroachment during the period October, 1951, to summer, 1957, averaged approximately 1200 feet per year in a northerly direction and 700 feet per year in an easterly direction in the vicinity of Port Hueneme and Oxnard.

13. It is feasible, from an engineering standpoint, to reclaim water from sewage discharged to the ocean by the City of Oxnard for cooling and other industrial purposes. In view of the poor mineral quality of the effluent, a major industrial market for direct use would have to be found before reclamation of water from the Oxnard sewage treatment plant effluent would be feasible.

14. The development of surface water supplies by the Santa Felicia Project on the Santa Clara River system and the Casitas Project on the Ventura River system will have a minor but beneficial effect on the mineral quality of surface and ground waters of the respective river systems.

15. In general, Colorado River water is similar in character and as good in quality as many of the ground waters presently found in Ventura County. Consequently, if Colorado River water were imported and used in Ventura County, it would have no detrimental effect on quality of local water provided favorable salt balance conditions are maintained by the importation of adequate quantities of water to assure the leaching and removal of salts from the several ground water basin systems.

16. Northern California water is of excellent mineral quality and of similar cation character to the water supplies of Ventura County. Importation of water from this source will have a beneficial effect on mineral quality if properly mixed with local supplies.

Recommendations

1. That in the operation of surface and ground water reservoirs in Ventura County, due consideration be given to the problem of salt balance so that the mineral quality of ground water supplies will be maintained and improved where necessary.

2. That the current programs of the responsible local agencies to halt the intrusion of sea water into the fresh water aquifers underlying the Oxnard Plain be fully supported and implemented as rapidly as possible.

3. That water well construction standards and abandonment procedures designed to prevent pollution and degradation of ground water by the interconnection of aquifers, be adopted and enforced.

APPENDIX A

MINERAL ANALYSES OF SURFACE WATERS, VENTURA COUNTY

Presented in this appendix are mineral analyses of surface waters derived from streams in Ventura County. Included in Tables A1 through A4 are all analyses of samples collected by the Division of Water Resources prior to May 1953, (and data procured from other agencies), except those published in Bulletin 46A of the Division of Water Resources 1933. All mineral analyses of surface waters which became available subsequent to 1952 are presented in Appendix G.

The analyses are tabulated according to drainage areas and in order of the stream sampling point number within these groups. The stream sampling point number is derived as follows: The State is divided into seven major hydrographic areas and into major stream basins of the State as defined in Bulletin No. 1, State Water Resources Board 1951. The first digit in the stream sampling point number designates the hydrographic unit in which the stream is located. The second digit (or two digits) designates the stream basin number within the major hydrographic unit. These basins are numbered, beginning with 1, at the most northerly basin in the unit, consecutively in a southerly direction. Thus 43 indicates the third major stream basin from the northern boundary of the fourth major hydrographic unit. Where a major stream basin applies to a group of streams instead of a single stream, a letter is assigned to each stream beginning with the northernmost stream and lettering consecutively southward. In a similar manner when a stream basin contained minor streams draining to the ocean, in addition to the principal stream, each of the minor streams is

assigned a letter beginning in the north. Thus, 43A is the northerly stream of the stream group in major stream basin 3 or it is the northerly minor stream draining to the ocean in major stream basin 3 which also contains major stream 3.

A sampling point on a stream is designated by the stream mile of the point above the mouth of the stream. A point on a tributary is designated by the stream mile of the major stream at the confluence of the tributary and the stream mile at the sampling point on the tributary above the confluence.

Examples:

43-3.0 - Santa Clara River, three miles upstream from mouth.

43-17.1-0.1 - Santa Paula Creek, one-tenth of a mile above its mouth which is 17.1 miles above mouth of Santa Clara River.

41D-2.5 - Padre Juan Canyon Creek, two and one-half miles above mouth.

All analyses in this appendix were conducted by the Department of Water Resources unless otherwise noted. All constituents in analyses run by the Department of Water Resources; U. S. Geological Survey, Water Quality Branch, Sacramento; Pacific Chemical Consultants; and Terminal Testing Laboratories, were determined using procedures given in Standard Methods for the Examination of Water and Sewage, American Public Health Association 1955 with the following exceptions: The Versenate method is used for calcium and magnesium determinations by all the laboratories. The Devarda Method has been used for nitrate by all laboratories except Terminal Testing Laboratory, and the United States Geological Survey.

Analyses obtained from the Santa Clara Water Conservation District and the Farmer's Irrigation Company reported the constituents in parts per million only, and the equivalents per million shown in the table were calculated by Department of Water Resources.

APPENDIX B

MINERAL ANALYSES OF GROUND WATERS, VENTURA COUNTY

Presented in this appendix are tables of mineral analyses of ground water samples collected from wells and springs in Ventura County. Tables B1 through B17 contain all data available prior to May 1953, including analyses of samples collected by the then Division of Water Resources and data obtained from other agencies. Data published in Bulletin 46A, Division of Water Resources, 1933 are not included. Tables B1 to B16, inclusive, present mineral analyses by ground water basin for each of the 16 basins in Ventura County arranged according to State well number. Table B17 presents available data on "Trace Constituents in Ground Water" for the entire county. All mineral analyses of ground water which became available subsequent to 1952 are presented in Appendix H.

All analyses are by the Division or Department of Water Resources unless otherwise noted. Methods of analysis are the same as shown in Appendix A, page A-2, except for those analyses presented in Table B17. Analyses in this table by the City of Los Angeles, Department of Water and Power, were determined by emission spectrograph and are accurate to plus or minus 50 per cent of the values shown. Data from U. S. Geological Survey, Water Quality Branch, Sacramento, were analyzed by procedures presented in Standard Methods for the Examination of Water and Sewage, American Public Health Association 1946[22] except as follows: Copper - Bis-Hydroxyethyl-Dithiocarbamate; Lead - Dithizone; and Zinc - Dithizone.

Data obtained from the Santa Clara Water Conservation District and a portion of that obtained from the Ventura County Farm Advisor reported constituents in parts per million only. Equivalents per million

for these analyses were calculated by the Division of Water Resources.

In Tables B1 through B17 analyses from wells in the Ventura and Santa Clara River Hydrologic Units, located within the watershed boundary of a ground water basin, but outside of the boundary of the more prominent aquifers, were placed at the end of the table and classified as tributary to the ground water basin. In Tables BB1 through BB17 analyses from all wells located within the watershed boundary of a ground water basin are included as wells in the ground water basin. Classification of wells as to aquifer or aquifers of production is by the Department of Water Resources, based upon well logs and water analyses.

a. Analysis obtained from Santa Clara Water Conservation District, unless otherwise noted.
b. Analyzed by Department of Water Resources.
c. Analyzed by Fruit Growers Laboratory, Incorporated.
e. Pump started 0800 January 1, 1951 and pumped continuously for 24 hours. A sample was collected every four hours.
f. Pump started 0800 March 22, 1951 and pumped continuously for 42 hours. A sample was collected every six hours.
g. Sampled after pumping 12 minutes.
h. Sampled after pumping 10 minutes.
j. Sampled from storage tank; well not pumped for one week.

APPENDIX D

MINERAL AND SANITARY ANALYSES OF EFFLUENT FROM SEWAGE TREATMENT PLANTS, VENTURA COUNTY

Presented herein are detailed mineral analyses of sewage effluents discharged from treatment facilities in Ventura County. Analyses are tabulated in descending order with respect to plant location and elevation within each hydrographic unit, that is, analyses for the upstream plants are entered first. For plants located on the Oxnard plain near the ocean, analyses for the most northerly plants are presented first.

All analyses are by the Department of Water Resources unless otherwise noted. Methods of analysis used by the Department and Pacific Chemical Consultants are the same as shown in Appendix A, page A-2. The type of sample analyzed is identified as either grab or time composite. A grab sample is one sample taken at one momentary interval of time and is representative of conditions and composition for only the time at which it is taken. A series of grab samples may be combined (usually in proportion to the rate of flow) to form a composite sample which is usually more representative of the average composition.

Tabulated values have been rounded off in some instances from the original reported values. For the constituents calcium through nitrate, values in parts per million have been rounded off to the nearest whole number and values in equivalents per million have been rounded off to the nearest hundredth. Fluoride concentration in parts per million has been rounded off to the nearest tenth. Trace (Tr) in Table D1 indicates a reported value less than five-tenths part per million or less than five-thousandths equivalent per million.

Each analysis of trace constituents presented in Table D2 was determined on the same sample for which a mineral analysis appears in Table D1. All of the trace analyses in Table D2 were performed by the California State Department of Public Health.

The time of sampling is given in Pacific Standard Time using a 24-hour system.

EVALUATING THE QUALITY OF IRRIGATION WATERS IN VENTURA COUNTY

L. D. DONEEN[1]

Introduction

Due to the tendency for salts to accumulate in irrigated soils, some authorities have questioned the permanency of irrigated agriculture. History of irrigated projects in the Western United States and abroad has shown the need for careful attention to the kinds and amounts of soluble material in irrigation waters. The accumulation of salts is largely determined by the irrigation water. Many of our rivers are low in dissolved salts, while others contain an appreciable quantity, particularly when degraded by return flow from upstream irrigation projects. The greatest extreme in salt concentration is found in waters from our wells. The salt content of the well waters in Ventura County varies from 1/4 to 4 tons per acre-foot. The application of 3 feet of water per season will add from 3/4's to 12 tons of salt to the soil. As most of the irrigation water in this County is pumped from wells with a moderately high salt content, the author, in cooperation with the Division of Water Resources and the University of California Agricultural Extension Service Office in Ventura County, made a survey of the salt damage to the more sensitive crops (lemons and oranges) grown in the County. This survey was made to check the validity of a recent classification for salines in irrigation water[3] and its application to Ventura County waters.

For some years the technical personnel in California interested

(1) Professor of Irrigation, University of California, Davis, California.

in irrigated agriculture have been concerned with the quality of water used in irrigation and from time to time have set up tentative standards as a guide to its quality. One of the standards more recently established and widely distributed in California is given in Table 1.

If a water has one constituent which falls in a lower class, as listed in Table 1, it automatically is placed in that class, although probably not of as poor a quality water as one having two constituents in the class.

Table 1--Qualitative Classification of Irrigation Waters[a]

	Class I Excellent to good	Class II Good to Injurious	Class III Injurious to Unsatisfactory
$K \times 10^5$ at 25°c[b]	Less than 100	100 - 300	More than 300
Boron, ppm[c]	" " 0.5	0.5 - 2.0	" " 2.0

Chloride, m.e.[e]	" " 5	5 - 10	" " 10

a. By L. V. Wilcox and O. C. Magistad, "Interpretation of analyses of irrigation waters and the relative tolerance of crop plants", mimeographed by the U. S. Regional Salinity Laboratory, 1943. Remimeographed by Agricultural Extension Service, University of California, 1944. Remimeographed by the Division of Irrigation, University of California, 1950 and 1952.

b. Specific electrical conductance ($K \times 10^5$ at 25°C). This measurement is reported in reciprocal ohms per cm., multiplied by 10^5(100,000), and provides an index of total dissolved electrolytes or total salinity. Dividing the conductance ($K \times 10^5$ at 25°C) by 10 gives an approximation of the salt content in milligram equivalents per liter. Multiplying the conductance ($K \times 10^5$ at 25°C) by 7 gives a rough estimate of parts per million (ppm) total salts.

c. Boron is expressed as parts per million (ppm) of the element.

d. Sodium percentage is computed by the formula $\frac{Na \times 100}{Na + Ca + Mg}$, when these are expressed as milligram equivalents (m.e.) per liter.

e. Chloride is expressed as milligram equivalents (m.e.) per liter.

Because of diverse climatological conditions, crops, and soils in California, it has not been practical to establish rigid limits for all conditions. Instead, field experience has indicated the classification shown in Table 1 should be used for the purpose of orientation and as a guide and that local conditions must be considered in judging the suitability of water for irrigation. The classification shown in Table 1 is the result of the research and experience of various investigators at the University of California, and the former Rubidoux and the U. S. Salinity Laboratory of the U. S. Department of Agriculture. Other classifications for irrigation water have been suggested and these have been listed in another paper[3].

Source of salines. The classifications for irrigation water described above have relied on electrical conductance as the criterion for total salt. The concentration range is from 100, K x 10^5 at 25°C (1,000 micromhos) or below for the best quality to 300 or above for the poorest quality water. The author's experience has been that the electrical conductance of an irrigation water is not a good measure of the potential accumulation of salines in a soil.

When nonsaline soils, irrigated for some years, gradually develop a high salt concentration, it is usually due to the accumulation of soluble salts brought in with the irrigation water. Under high water table conditions the soluble salts from the deep subsoils may be carried to the soil surface with the rise of the water table. Some salt may be dissolved from the soil minerals and with a high water table their removal by leaching is prevented. However, these are probably a minor source, and much of the salt increase may be attributed to that in the irrigation water. In the absence

of a high water table, the irrigation water would be the main source of salts in the development of a saline soil.

A number of workers have shown the soil solution in well drained soil to be more concentrated than the irrigation water used. Under this condition Scofield [8], 1935, estimates that the soil solution in heavily leached soil may be twice as concentrated as the irrigation water, and under less severe leaching where the water is used sparingly the difference is much greater, often 8 times or more the concentration of the irrigation water. This concentration of salts in the soil is due to two factors; evaporation from the soil surface and water used by the plants in transpiration. The plants usually remove only a small percentage of the total salt occurring in the irrigation water.

Investigators of alkali reclamation and related fields recognize the limited solubility of calcium and magnesium carbonates and calcium sulfate, but the application of this knowledge has not been made to irrigation waters. This investigation is concerned with these slightly soluble salts which may occur in the irrigation water and their ineffectiveness in the potential salination of a soil. These salts of limited solubility do not contribute to the formation of saline soils.

Theory of Effective Salinity

Effective salinity of irrigation water. In this study let us assume the following conditions prevail: The irrigated soil is in a low rainfall area, and no extensive leaching of the soil occurs from application of more water than will be lost by surface evaporation or vegetative transpiration. These conditions are usually found in soils

with a hardpan, claypan, or high water table, frequently in highly stratified, heavy clay soils, and in permeable soils where the water is used sparingly. The salts from the irrigation water will accumulate in the soil. As the soil solution becomes concentrated, certain salts will precipitate. Because of the low solubility, the order of precipitation will be calcium carbonate followed by magnesium carbonate and then sulfate. Other salts, such as calcium chloride, magnesium chloride and sulfate; and sodium chloride, sulfate, and bicarbonate, occurring in irrigation water in any significant concentrations are extremely soluble and accumulate in the soil solution. Eaton[5], 1950, discussed the calcium and magnesium carbonate precipitation as it effects the sodium percentage in the soil solution. However, Joseph[6], 1925, working with the irrigation waters of the Blue Nile, points out that calcium carbonate should not be included as "permanently soluble material" in the formation of alkali soils because of precipitation by evaporation.

The most soluble salt to precipitate is the calcium sulfate with a solubility in pure water of about 28 m.e. per l.* or 2,410 ppm. The solubility of this salt is high when compared to calcium and magnesium carbonates but not sufficiently soluble under our present standards to produce a saline soil. Many of our salt-sensitive plants grow satisfactorily in gypsiferous soils. To be sure, gypsum (calcium sulfate) in the irrigation water or in the soil will contribute to the extent of its solubility (2,410 ppm) in the salination of a soil. Other soluble salts in the soil solution will influence the solubility of gypsum, and also calcium and magnesium carbonate.

* Recently the term "equivalents per million" has been used by some groups and individuals in reporting water analyses. This method of reporting is nearly the same as that for milligrams equivalent per liter, and for all practical purposes these terms can be interchanged.

High concentrations may increase the solubility of gypsum by several m.e. per l. and extremely high concentrations of salt may increase the solubility by 50 per cent or more. When the sulfate or calcium ion predominates in a saline soil solution, the common ion will suppress the solubility of gypsum, and under certain conditions they may amount to a third or more based on its solubility in pure water. These same general principles hold for the solubility of calcium and magnesium carbonate. Calcium sulfate alone or in combination with other salts will not in itself bring about a saline soil.

Calcium and magnesium carbonate and calcium sulfate should not be included in establishing standards for salinity as is now the practice in the use of electrical conductance. The remaining soluble salts forming salinity are listed as "effective salinity" of an irrigation water in Table 2. For example, water number 1 has a conductance of 103 with a 12.2 m.e. per l. total salt. Upon concentration of this water in the soil solution, the calcium would precipitate as the carbonate, followed by the precipitation of magnesium carbonate. As there is more bicarbonate than calcium and magnesium, these two cations would not contribute to salinity and are subtracted from the total cations leaving 3.6 m.e. per l. of soluble salts or "effective salinity". Thus the salinity potential of this water is reduced from 12.2 m.e. per l. salt to 3.6. This water has been used many years on well drained soil without serious problems of salt accumulation.

b. Figures underscored indicate these ions will precipitate as the soil solution is concentrated.

c. Asterisks following figures indicate these ions will only partially precipitate as the soil solution is concentrated.

Water number 2 is a high sulfate water with a total cation content of 23.4 m.e. per l. The first precipitation in this water would be the bicarbonate as calcium carbonate. As there is an excess of calcium over bicarbonate, no magnesium precipitation would be involved. The remaining calcium would precipitate as the sulfate, and the salinity of the water would be reduced by the calcium precipitation to 12.3 m.e. per l. After this water was used on a loam soil for 7 years the salinity had increased to a concentration that reduced potato yields by 50 per cent, and it was difficult to obtain uniform germination of seeds. Deep percolation of irrigation water was difficult due to clay lination in the subsoil; consequently much of the salt added remained in the surface three feet of soil.

Water number 3 has a high salt content with a conductance of 330 and a total ionic concentration of 42.9 m.e. per l. The reduction in concentration would be by precipitation of calcium carbonate and sulfate. Due to the high calcium content the reduction in salinity is determined by the bicarbonate and sulfate ions for a total of 26.5 m.e. per l. leaving in solution 16.4 m.e. per l.effective salinity. This water was applied sparingly on a sandy loam soil and crop yields were reduced by the accumulation of salines.

The three waters discussed above show a marked reduction in potential salinity, "effective salinity", which is not taken into consideration in the classification listed in Table 1 and consequently this Table is not applicable in estimating the salination of a soil by an irrigation water. Even with the reduction in potential soil salinity of the above waters, two of them produced saline soils because of the relatively high effective salinity and insufficient leaching of the soil.

Some waters precipitate few salts upon concentration in the soil solution, such as water number 4. In this example the reduction in salinity is by the precipitation of 2.9 m.e. per l. calcium and magnesium carbonates from a total salinity of 29.4 m.e. per l. giving 26.5 m.e. per l. effective salinity. With this water the conductance or total concentration would be a fair measure of effective salinity.

The calculation of effective salinity is more applicable to waters of low salt content, i.e., waters with a conductance of less than 100, than those of a higher salt concentration as these waters are recognized frequently as possibly harmful for some or all crops. Waters 5 and 6 with a conductance of 75 and 6_, respectively, and approximately the same total salt concentration, have widely different effective salinities. Number 5 water has a high percentage of the total salts occurring as effective salinity (6.3 m.e. per l.) whereas number 6 is reduced to approximately a third (2.3 m.e. per l.). Additional samples of varying effective salinity in low salt waters of nearly the same total salt concentration are numbers 7, 8, and 9. The effective salinity ranges from 4.2 to 5.8 of a m.e. per l. The above examples indicate that the potential salinity of a water for irrigation cannot be judged by conductance or total salt content, and the slightly soluble salts of calcium and magnesium carbonates, and calcium sulfate should not be considered in classification of water for accumulation of salines in the soil.

Four surface waters diverted from rivers or streams in California for irrigation purposes are listed in Table 2. These show a reduction from total salts, when calculated as effective salinity, of 34 per cent in river water number 2 (San Joaquin) to 67 per cent for number 4, Cache Creek. With the exception of number 4, these waters give rise to soil salinity when deep

percolation is impaired. Notable is the accumulation of salt in the Imperial Valley from Colorado River water, number 3. This water has an effective salinity of 7.0 m.e. per l. which is sufficiently high to account for all the accumulated salts of Imperial Valley.

Salination of a soil by irrigation water. For irrigation waters an approximate relationship exists between conductance, parts per million, milliequivalents per liter and tons of salt per acre-foot. For example, a conductance of 1,000 micromhos is approximately equivalent to 700 ppm, 10 m.e. per l. total salt, or a ton of salt per acre-foot. These are very useful relationships in expressing total salts of an irrigation water in various terms. However, in the precipitation of calcium and magnesium bicarbonates and calcium sulfate, most of the salts of high molecular weights are removed from solution, which changes the relationships that existed in the original irrigation water. A better relationship for effective salinity would be one milliequivalent to equal about 55 ppm or 150 pounds of salt per acre-foot of water. Then 10 m.e. per l. effective salinity would be approximately 550 ppm or three-fourths ton of salt per acre-foot of water. Assuming the salts of an irrigation water remain in the soil to the depth of plant rooting, then the degree of salination will be in proportion to the quantity of water used in evapotranspiration and the effective salinity of the irrigation water.

If 0.2 per cent by weight of dry soil is used as a criterion for the limit between saline and nonsaline soil, then to bring an acre-foot of soil to this concentration would require 7,140 pounds of salt. (When 4 millimhos, 10^3, of the saturated extract is used as a standard

for the lower limits of salinity, the total salt is about 6,000 pounds or 0.18 per cent dry weight for soils of intermediate water-holding capacity).

As each milliequivalent effective salinity contributes about 150 pounds of salt per acre-foot of water, it would take 48 m.e. per l. to bring each acre-foot of soil to 0.2 per cent salt, or a water containing 10 m.e. per l. effective salinity would require 4.8 acre-feet to reach this salt percentage. If the rooting depth of the plant is 6 feet and salts are not leached from this rooting zone, then 10 m.e. per l. of effective salinity would require 28.8 acre-feet of water. Assuming this is applied at the rate of 2 1/2 feet per year, it would require approximately 11 years to salinize a soil uniformly to 0.2 per cent salt (this is an idealized situation as field soils are rarely ever uniformly salinized). The depth of soil or the depth of rooting of the plant species involved would determine the number of years required to salinize a soil provided leaching was not involved.

Criteria for effective salinity. The above calculations assumed no leaching of a soil below the root development of the plant. Under field conditions this would not normally occur. Under most situations in the field, the irrigation usually results in some movement of soil moisture below the root zone. Irrigated high water table soils frequently have a natural or artificial drainage system. Although all the accumulated salts are not removed in the drainage water, a balance may be established so that the accumulation of salines is held at a concentration sufficiently low to permit the growth of agricultural plants. The salts in some high water table areas may not be due entirely to the effective salinity of the irrigation water but may have been in the original soil before irrigation was started or, as some authorities have suggested, may

have been brought up from salt previously deposited in the deep subsoil by the rise of the water table. Under these conditions any effective salinity of the irrigation water will only aggravate the salt condition of the soil.

Many other conditions may seriously reduce deep percolation of the irrigation water in a reasonable time such as high sodium soils, stratified soils, clay lenses, some clay and adobe soils, dense or compact subsoils, and heavy clay subsoils. These soil conditions may prevent sufficient leaching to remove the salines of the irrigation water. However, some leaching may be accomplished by holding the water on the surface for a long period of time. An extreme example would be the removal of salines on very heavy soils by growing rice in which the soil is submerged for about 5 months. Most hardpans and some claypans are practically impermeable to water. Even these may have cracks or ruptures through which water and accumulated salts may drain.

Under conditions of restricted drainage different standards should be established for effective salinity of an irrigation water than with deep, open soils where leaching is easily accomplished. Table 3 suggests tentative standards for effective salinity of the irrigation water with and without restricted drainage. The assumption is made that 1 to 2 m.e. per l. of effective salinity will be removed in crop production.

Table 3. Tentative Classification for Effective Salinity of Irrigation Waters

Soil Conditions	Terms used	Class 1	Class 2	Class 3
Little leaching of the soil can be expected, due to low percolation rates	m.e. per l.	<3	3-5	>5
	ppm	165	165 - 275	275
	lb. per ac-ft.	450	450 - 750	750
Some leaching but restricted. Deep percolation or drainage slow.	m.e. per l.	<5	5 - 10	>10
	ppm	275	275 - 550	550
	lb.per ac-ft	750	750 - 1500	1500
Open soils. Deep percolation of water easily accomplished.	m.e. per l.	<7	7 - 15	>15
	ppm	385	385 - 825	825
	lb. per ac-ft.	1050	1050 - 2250	2250

The crucial concentrations are those listed in Class I for the three soil conditions. Classes II and III indicate increasing concentration, and the build-up of soil salinity should be checked periodically and irrigation practices adjusted to remove salinity with the minimum loss of water. Class I water is not considered safe under all extreme conditions encountered in the field. Other than those listed in Table 3, the circumstances under which an irrigation water is to be used should be taken into consideration. In areas of high annual rainfall where the soil is wet to 6 feet or more in depth, or below the depth of rooting of the crop grown, the concentration of effective salinity could be increased for all classes. In low rainfall areas some

leaching may be desirable, but due to the low farm irrigation efficiencies, ranging from 20 to 80 per cent of the water delivered to the farm, most surface soils are adequately leached for removal of any excess salts. In fact, overirrigation or low farm irrigation efficiencies have resulted in damage to more soils due to the rise of a water table with increased salinity than irrigating sparingly and allowing the salts to accumulate.

In pumped areas where the water table is low, water is used sparingly, and the water contains high effective salinity, an occasional overirrigation may be beneficial in removing salines. Only a few isolated cases are known to the author in which serious salinity problems have developed due to the use of irrigation water with a relatively high salt content in the absence of a high water table. Careful investigation should be made to determine whether sufficient deep percolation is taking place in the ordinary irrigation practice to remove the salts from the surface soil. Where surface water is used for irrigation and the potentiality of developing a high water table may exist, irrigations should be limited to evapo-transpiration with the minimum of excess water to remove the salines.

Application of Effective Salinity

Ventura County irrigation waters. In the spring of 1953 and again in the fall a detailed investigation was made of salt injury to lemons and oranges, two of the more sensitive crops grown in the County. As a basis for this study, 375 irrigation waters from widely distributed agricultural areas of the County were used. A classification of these

waters, percentage-wise, for total salinity and effective salinity is given in Table 4. This table is based on the standards for quality of water given in Table 1.

Table 4. Percentage Distribution of 375 Irrigation Waters in Three Classes, Based on Table 1, for Total Salinity and Effective Salinity

	Class I Less than 10 m.e. per l.	Class II Less than 30 m.e. per l.	Class III More than 30 m.e. per l.
Total salinity	16	77	7
Effective salinity	67	32	1

Applying these standards to effective salinity, it was found that 67 per cent of the waters were in Class 1, whereas on the basis of total salinity, only 16 per cent were in this class. If the criterion given in Table 3, is used 44 per cent of the waters are below 7 milliequivalents per l., 46 per cent between 7 and 15 milliequivalents and 10 per cent above 15 milliequivalents per l. For the 375 waters the average reduction from total salts to effective salinity is 48 per cent.

The above discussion has been limited to the accumulation of total salines. Other factors should be considered in the classification of irrigation waters, particularly sodium. The average sodium percentage of the total cations based on the formula given in Table 1, for the 375 waters is 29 per cent with only 5 waters above 60 per cent sodium and only one of these above 70. The per cent sodium of the effective salinity is increased when compared to the natural waters due to the precipitation of some of the calcium and

and magnesium salts as indicated in the last column of Table 2. The average per cent sodium of the effective salinity for the 375 waters is 56 per cent and is below the maximum allowable standards of 60 per cent sodium given in Table 1. However, 31 per cent of the waters were above 60 per cent sodium with 18 per cent of the water being between 60 and 70 per cent sodium, 6 per cent of them between 70 and 80, 2 per cent between 80 and 90, and 5 per cent between 90 and 100 per cent sodium.

The question arises, will the waters above 60 per cent sodium, based on effective salinity, have an adverse effect on soil structure such as dispersal of the clays accompanied by impaired water penetration? The answer, pertaining to these waters of Ventura County, seems to be no. Eighty per cent of the 375 waters precipitate calcium sulfate (gypsum) upon concentration in the soil solution. As calcium sulfate has a solubility of 28 m.e. per l., this concentration will always be present in the soil solution. Doubling this concentration with sodium salts will bring the concentration well above the saline range of 4 millimhos and only increase the sodium to 50 per cent of the cations. These waters also have an appreciable quantity of magnesium, ranging from about 1 to 20 m.e. per l. with an average of 4.3, which remains in the soil solution when calcium sulfate is precipitated. The problem would not be one of high per cent sodium, but one of total salines. Assuming the concentration of salts continues to increase above the lower limits established for a saline soil, even though the sodium percentage increased, a maintenance of good soil structure would result due to the high concentration of soluble salts.

Of the waters not giving a calcium sulfate precipitation (20 per cent), 16 per cent had sufficient bicarbonate to precipitate all the calcium and only part of the magnesium, while approximately 4 per cent or 8 waters of the 375 precipitated all the calcium and magnesium and had an excess bicarbonate which forms sodium bicarbonate. Eaton[5] listed these as "residual sodium carbonate". As the bicarbonate equals or exceeds the calcium and magnesium concentration, sodium of the soil solution will replace calcium of the cation exchange, which provides available calcium to precipitate with the excess bicarbonate. Recent investigations by Chimondes[2] show that concentrating residual sodium carbonate waters will enrich the cation exchange with sodium and at the same time give a precipitation of calcium carbonate.

Only two of the 8 waters had residual sodium of more than 1.5 m.e. per l., these being 2.5 and 3.1. The numerous farms visited showed no evidence of soil structure deterioration due to sodium in the irrigation water.

The Effect of Ventura County Irrigation Waters on Citrus and Soil

This study was limited to 20 citrus groves, as they constitute one of the major crops of this County and are considered to be very salt sensitive, especially the lemon. The areas having excess boron were not included in this study. The survey included a comparison of leaf injury, or burn, with the effective salinity of the irrigation water and with the soil type to a depth of 3 feet which contains the major concentration of citrus roots. These soils are classified as the Yolo Series, without lime accumulation and are well drained. Besides the above-mentioned variables, there is the unknown factor of the farmer's irrigation practice.

Irrigation Waters. The selection of the groves for study was made on the basis of total concentration of salts in the irrigation water; ranging from the lowest 11.32 to the highest 36.6 m.e. per l. in concentrations of water used for irrigation of citrus in the county, Table 5. The per cent sodium of the total cations is not considered high. The effective salinity for most of the waters is approximately half the total salts, and the average reduction for all waters was 46 per cent.

Table 5. Analyses and effective salinity (Eff. Sal.) of irrigation waters used on Citrus Groves and Salt Injury rating of the trees, Ventura County. 1953.

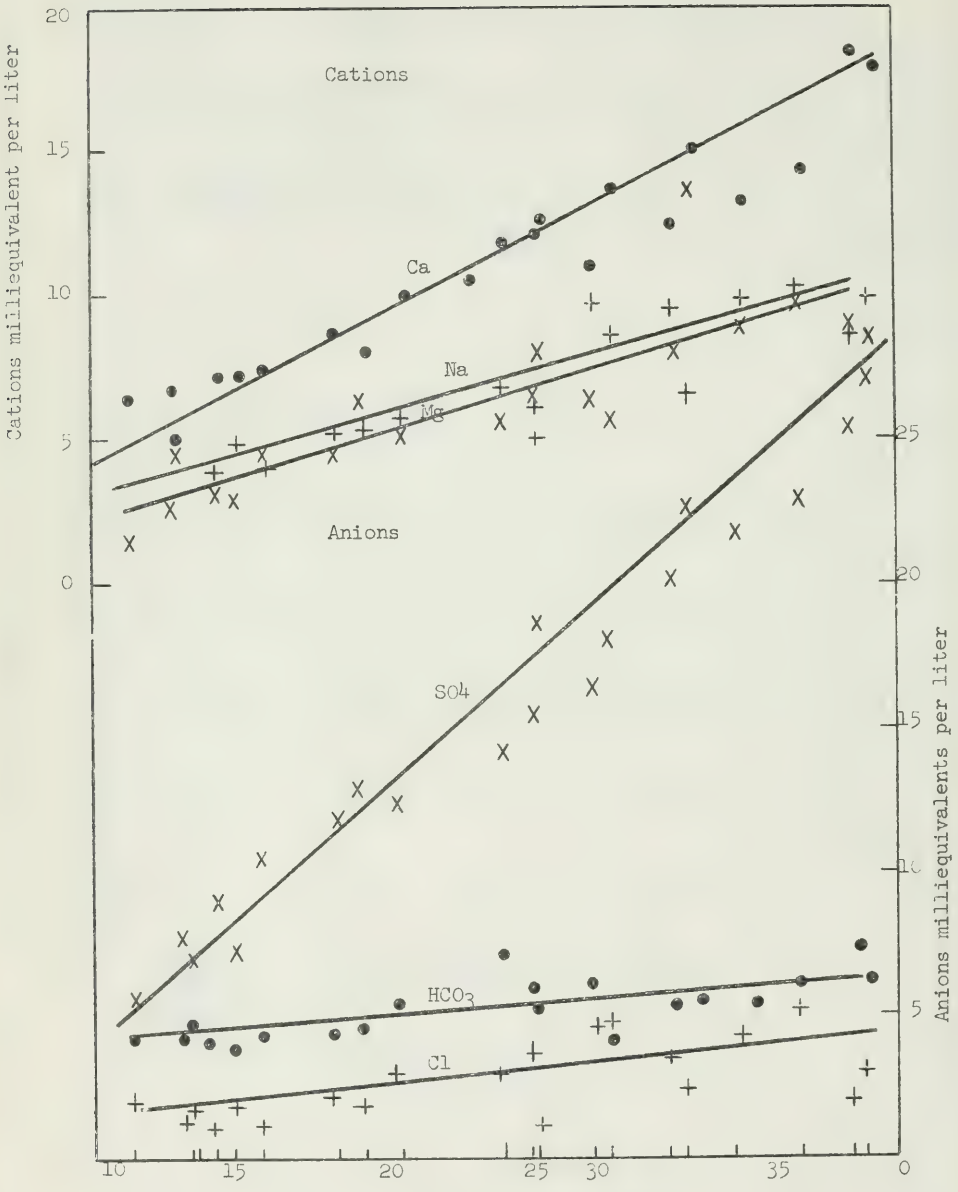
*1 - Very slight tip burn on second year leaves
2 - Some tip burn and marginal injury on second year leaves
3 - Moderate tip burn and marginal injury on second year leaves
3+ -Severe salt injury, and trees lacked vigor

The relationship of the cations and anions to the total salt concentration of the irrigation waters is given in Figure 1. The sulfate ion is closely related to total concentration, whereas the bicarbonate and chloride is relatively constant. Calcium showed the same trend as the sulfate but to a lesser degree. Sodium and magnesium increase with total concentration, but considerably less than calcium.



Total milliequivalents per liter

Fig. 1 - Relationship of individual ions to total concentration of Ventura Irrigation Waters.

The salt injury rating, Table 5, is classed from 1 to 3 according to the judgment of citrus experts. Rating 1 is for the slightest tip burn on the second year old leaves while rating 3 shows tip burn and some marginal burn for these leaves. Rating 2 is intermediate between 1 and 3. Even the salt injury in rating 3 was not considered sufficient to cause a reduction in yield. On Grove 20, rated 3+ a definite reduction in yield occurred and the trees were yellowish in appearance and lacked vigor.

Soil Salinity and Lime Accumulation from Field Irrigation. The 20 groves consisted of well established older trees. With the exception of Grove No. 1 all were furrow irrigated. Some with permanent furrows, while others were clean cultivated with the furrows remade several times a year. Grove No. 1 had been sprinkle irrigated for a number of years. The soil was sampled in foot depths to three feet for salt analysis, and accumulated lime. The sampling location was at the periphery of the tree and approximately 15 to 18 inches from the center of the outside furrow - the one next to the tree. This should be in the range of capillary movement of moisture from the furrow, and therefore in the area of highest salt concentration.

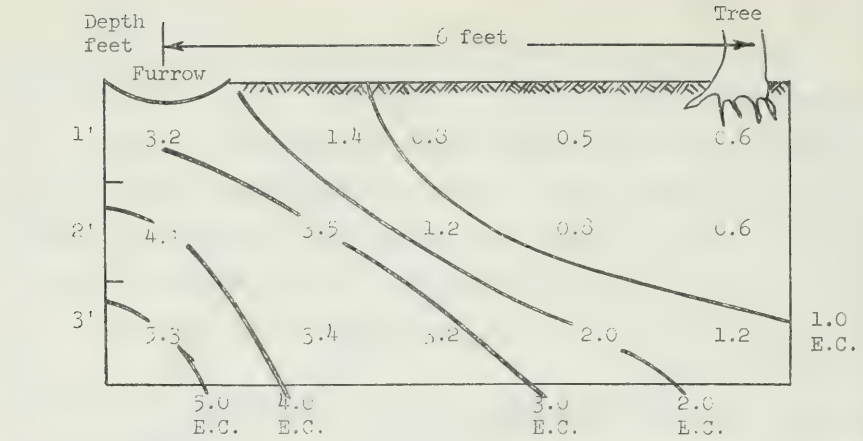


Fig. 2. Salt accumulation in soil of a lemon grove from irrigation water No. 10, Eff. Sal. 12.2 (Table 5). E. C. X 10^3 of saturation extract.

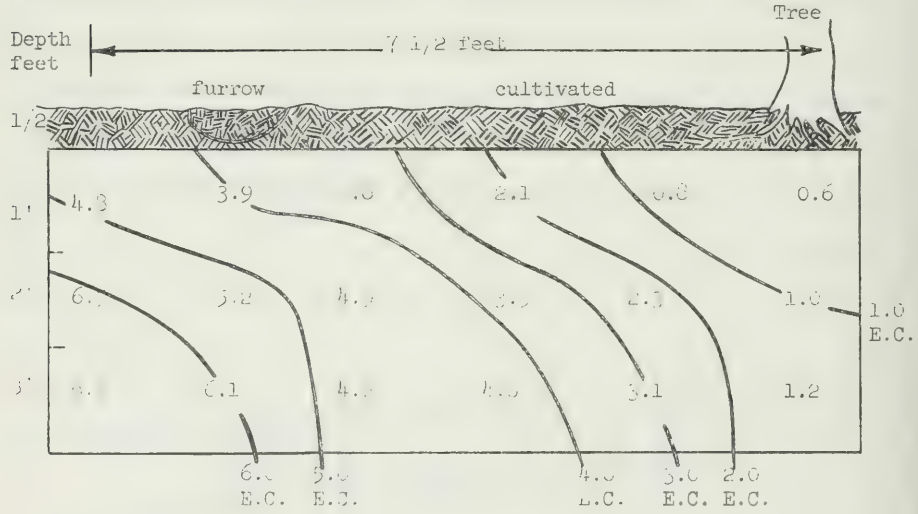

Fig. 3. Salt accumulation in soil of an orange grove from irrigation water No. 17, Eff. Sal. 18.9 (Table 5). E.C. X 10^3 of the saturation extract.

A detailed survey of salines in the soil profile from the outside furrow to the tree row is given in Figures 2 and 3 for Groves Nos. 10 and 17, and illustrates the accumulation of salines from the irrigation water. The soil profile in the tree rows parallel to the furrows is low in salt and in most cases receives no irrigation water other than from rainfall. The lime accumulation follows the same general pattern but with less variation in amounts from the tree row to the furrow. When the trees are small the furrows are placed close to the tree-row, and as they increase in size the furrows are gradually moved farther from the row. As lime is only slightly soluble, it has remained in the soil near the tree, while the accumulated salines have been leached to a lower depth by an occasional high rainfall year.

The accumulation of soluble salines, per cent sodium, lime content, and the soil texture are given in Table 6. The groves are numbered the same as those listed in Table 5. A complete analyses was made of the saturated extract, but only a summary is presented of total salts in m.e. per l. and per cent sodium of the cations. The sodium percentage of saturated extract is considered relatively low and, in general, is in the same percentage range as that of the irrigation waters, Table 5. The lime ($CaCO_3$) is based on the per cent dry weight of soil. The soil was originally classified, in 1917, as the Yolo series free of lime except in poor drainage and alkali areas, which were not covered in this investigation. The soil texture by depth was determined from the soil survey of 1917, the observations made in the field at the time the soil samples were secured, and from the moisture equivalent of the soil. The water holding capacity of the soil may be judged from the moisture equivalents. For sandy loams, the moisture-equivalent ranged from 4 to 6 per cent, fine sandy loam from 6 to 10, loams from 12 to 17, silty loam from 18 to 22, silty clay from 24 to 29, and clay from 28 to 32 per cent moisture.

Evaluating Ventura County Irrigation Waters for Citrus. The use of these waters has not deteriorated soil structure. This was noted in all groves visited and is further indicated by the low sodium percentage of saturation extract, Table 6.

On these permeable soils, little or no injury to lemon leaves was noted when the effective salinity was at or below 7 m.e. per l., as established in Table 3. One exception was noted, Grove No. 2, where a water containing 6.5 m.e. per l. effective salinity was applied to a soil

classed as loam in the surface 2 feet, clay in the third foot, and below this an exceptionally heavy subsoil. A heavy deposit of lime and gypsum was noted in the 3 and 4 foot depths, Table 6, and a slight to moderate amount of injury, or "burning" was noted. In an adjoining grove using the same water but in the absence of the heavy subsoil, no injury to the leaves was observed. Wherever subsoils of low permeability were encountered the salt injury was more severe than on soils of uniform texture. Although internal drainage was considered good, the leaching of salts through the heavy subsoil was not always accomplished by the irrigation practiced. On soil of uniform texture, particularly the sandy and loamy phases, little injury was noted up to 10 m.e. per l., effective salinity, but a moderate amount of burn at 12 m.e. per l. was observed. On the sandy and gravelly soils, where some leaching nearly always occurs during each irrigation, little salt injury to the leaves was observed with concentrations as high as 12 m.e. per l.

Once these soil conditions were established with the allowable effective salinity mentioned above, injury to the leaves was in direct proportion to increased effective salinity of the irrigation water. The soil type coupled with the effective salinity listed above cannot be adhered to as a rigid classification. Occasionally leaves would show some tip burn and a slight marginal burn but not sufficiently severe to affect the vigor of the tree or cause a reduction in yield. During dry years, when the rainfall does not wet the soil below the depth of rooting and there is a shortage of irrigation water, the salt injury is more severe and widespread than during years of normal or above average rainfall. In dry years some tip and marginal burning of the leaves may occur at 7 m.e. per l. or less of effective salinity. Considering all factors involved, 7 m.e. per l., effective salinity seems to

be a logical choice for the division between Class I and Class II water for a sensitive crop, such as lemons, under irrigation practices of Ventura farmers.

Since oranges are more salt tolerant than lemons under similar soil conditions, the standard could be raised from 3 to 5 m.e. per l. of effective salinity. Very little if any burning of orange leaves was noted below 10 m.e. per l. and usually only a moderate amount of injury with effective salinities of 15 to 18 m.e. per l.

Relative salt tolerance may be studied where lemons and oranges are interplanted in the same grove. Here, irrigation practices would be the same. One such grove, not listed in the tables, with a gravelly type soil on unconsolidated rock subsoil and irrigated with water having an effective salinity of 11.8 m.e. per l. showed a very slight burn, -- only the very tips of a few orange leaves, whereas the lemons had a moderate to severe burn on most of the mature leaves. Another example is grove No. 12 where a few lemon trees were interplanted with oranges and irrigated with a water having 12.9 m.e. per l. effective salinity. The orange leaves showed a moderate amount of burn and the lemon leaves an extremely severe injury.

During the seven years previous to 1951-52 the rainfall in Ventura County was lower than normal, while the 1951-52 year was high, approximately 70 per cent above normal. When this survey was made in 1953 the precipitation was again low, being about 66 per cent of normal for the rainfall year 1952-53. The citrus plants in the County showed only a very small amount of leaf injury where water of 10 m.e. per l. or less was used for irrigation as noted above. This constitutes 67%

of the water used for irrigation. The remaining 33 per cent injured the leaves from a slight burn on the tip to the extreme condition of partly defoliating the tree as the effective salinity progressively increased. This is just about the ratio of burning observed in the survey. Approximately one-third of the groves showed from slight to extreme burning of the leaves. The other two-thirds showed no injury or not in sufficient amount as to be a factor in determining the vigor of the tree, or crop production.

Precipitation of lime and gypsum from irrigation water. The accumulation of lime and gypsum for bicarbonate-sulfate water is given in Table 6. With the exception of the gravelly and the very sandy soil, where every irrigation unavoidably is a leaching process, calcium carbonate has a tendency to precipitate. Regardless of the total concentration most Ventura County waters have about 5 m.e. per l. of bicarbonates and considerably more calcium, Figure 1.

A number of waters were concentrated in the laboratory at room temperature to determine their stability. In the following example, the water had a concentration of approximately 15 m.e. per l. The cations calcium, magnesium and sodium, and anions, bicarbonate, sulfate and chloride, each had a concentration of about 5 m.e. per l. Upon concentration all of the ions increase in direct proportion to the decrease in volume with the exception of bicarbonate and calcium, Table 7. Concentrating the water one time, or half of the original volume, precipitated 71 per cent of the calcium bicarbonate. For many soils this is the range between field capacity and the permanent wilting percentage.

Table 7. Precipitation of calcium bicarbonate by increasing concentration from evaporation.

Ions	Original Water	Concentration of Original Water							
		1/2		1		2		3	
		Theor.	Found	Theor.	Found	Theor.	Found	Theor.	Found

HCO_3 meq/L	4.7	7.1	2.8	9.4	2.5	14.1	2.4	18.8	2.3
% $CaCO_3$ ppt			59		71		82		86

This experiment was conducted with the partial pressure of carbon dioxide of the air. Soil atmosphere often contains a higher concentration of carbon dioxide because of root respiration and decomposition of organic matter. This would tend to hold the calcium bicarbonate in solution. However, for the 20 groves, the average soil solution at field capacity was 2.6 times the concentration of irrigation waters. If the soil moisture is reduced to near the permanent wilting percentage the average concentration of the soil solution increases to approximately 5 times that of the irrigation waters. Thus ample opportunity for precipitation of lime occurs except when the soil is frequently leached. With increased concentration of the soil solution, gypsum precipitates as indicated in Table 6. No doubt the farmer's irrigation practice determines to a large extent the accumulation of these precipitates. Nevertheless, they were almost always found in the stratified soils and where the subsoil was heavier than the surface, particularly if irrigated with water contained 10 or more m.e. per l., of salt available for precipitation. The presence

and the amount of the precipitated salts found in the soil may be used as a rough estimate of the frequency and quantity of irrigation water leached below the root zone of citrus, and also serve as a guide to irrigation efficiency studies.

Where lime and gypsum salts accumulated, they were usually visible upon examination of the soil. These salts were in the form of soft gray crystals or nodules. In some cases the deposits were in the form of streaks or layers that meandered through the soil mass. Occasionally these nodules or deposits were a 1/2 inch in diameter and usually encased an appreciable quantity of soil.

The above observation pertaining to the accumulation in the soil of the precipitates from Ventura County water may not be pertinent to their classification, but with continuous accumulation there may be eventually, and possibly at the present time, harmful effects in plant growth and yield. Most of the precipitation takes place near or around the roots of the citrus plants, and many of the roots are covered with a hard external covering, or outer shell, of lime and gypsum. Oftentimes the roots can be pulled from this depository shell leaving a long tube of the cemented soil particles. This crustation is not limited to the older roots but is found on the younger white roots. As citrus roots develop slowly with few fine fibrous roots, the question arises as to the effects of this crustaceous material around the roots on the nutrition and physiological processes of the plant. The author believes the vigor of the tree, and the size and quality of the fruit in relation to this crustification of the root system should be studied in addition to the meager observations listed above.

Recent reports. Since this investigation was started in 1953 several papers have appeared showing the accumulation of lime in soils irrigated with bicarbonate waters (1, 4, 9). These experiments were conducted in containers in the greenhouse using various bicarbonate waters. In two of the experiments (1, 9) a leaching regime was maintained, yet an appreciable accumulation of lime occurred. In an investigation on the effect of irrigation waters on soil in Idaho (7), the authors concluded that, calcium carbonate content of the soil showed an increase when irrigation waters high in calcium and bicarbonate are used.
